That the galvanic current often completely dissipates fibroid tumors of the uterus few will, I believe, affirm. In the treatment of scores of fibroids on the external surface of the body, I have never yet seen a single instance where one of them completely disappeared. As a rule, the reduction is comparatively slight, unless suppuration is excited, which may be easily done. External fibroids are simply unsightly, and for this reason we desire to be rid of them; and as it is not possible to obtain more than a reduction in size, the knife is to be preferred, and electrolysis has fallen into disuse. We treat uterine fibroids, on the contrary, not because they are unsightly, but because associated with them are a train of symptoms sometimes of the most distressing character. These symptoms can, it is believed, be relieved to a greater or less extent by electrolysis, and sometimes so completely relieved as to lead to the belief, so far as the patient is concerned, that the tumor has entirely disappeared. In the great majority of cases, however, it is simply a symptomatic cure. The tumor is still there, but reduced in size, and so far as pressure upon surrounding parts is concerned, or any hemorrhagic tendency, it is entirely harmless. I am a firm believer in the great utility of the galvanic current in the thickenings and infiltrations resulting from inflammation of the pelvic cellular tissue. For the absorption of old exudations in other parts of the body, this treatment has long been used with excellent results, and in pelvic exudations the results are even better. I have seen the treatment, persistently carried out, result not only in the absorption of large pelvic deposits, but in the cure of the most obstinate and severe sciatica, and in the restoration of power to partially paralyzed limbs. In such cases, both sciatica and paralysis are caused, undoubtedly, by pressure upon the pelvic floor, and can be relieved only through the dissipation of the morbid products.

There are two methods of action through which we obtain results from electrolysis. The first and most apparent is the absolute destruction of tissue which takes place at the time of treatment. Some suppuration may follow, and thus, by actual loss of substance apparent to the sight, the tumor decreases in size. If, however, these were the only active forces in the electrolytic process, the method would lose much of its effectiveness.

If this be not so, how can we account for the many well-attested cases where morbid growths have entirely disappeared under simple external applications? Herein is the difference between the electrolysis of organic and that of inorganic substances. In the electrolysis of inorganic substances the effects cease as soon as the current ceases, the substances remaining in the condition in which the current left them. The electrolysis of organic substances, on the contrary, starts a process that continues long after the current ceases to flow. Besides this subsequent effect, the current penetrates the tissue and induces various important changes beyond and beneath the eschar, and these combined agencies do far more, in many cases, to diminish the size of morbid growths and prevent further development than an actual destruction of a limited area.

Hitherto one important defect in the treatment of various uterine diseases, and especially morbid growths, has been the use of too weak currents. This has been due partially perhaps to a commendable caution in dealing with an agent so potent as electricity, but more to our lack of definite knowledge of the amount of current strength needed to accomplish certain ends, and our inability to readily command more than a certain limited working power from the apparatus in ordinary use. A third obstacle was the absence of any instrument by which the current could be accurately measured. The improved milliamperemeter has overcome this difficulty, and is indispensable in all electro-surgical operations, besides being a vast aid in all electro-medical applications. Instead of a strength of current equal to only ten to thirty milliampères, which was commonly used, and which indeed was all that could be obtained from the appliances in use, it is now no uncommon thing to use currents of even several hundred degrees of strength.

For this purpose the external electrode must not only be material of the best conduction possible, but of suitable size and sufficiently flexible to be perfectly adjusted to every inequality of surface which it covers. The strength of current from a given number of cells is in proportion to the size of the electrodes, and therefore, when from a certain number of cells it is desired to get the greatest strength possible, the electrodes should be of the largest size convenient for our purpose. As to the quality of the electrodes, sponges are too bulky and offer too great resistance when our object is strength of cur-

rent. As a substitute Apostoli suggested sculptors' clay held in place by gauze.

This material holds moisture fairly well, can be adapted closely to the skin, and is undoubtedly an admirable electrode. An electrode that answers well, however, for the ordinary purposes of local application consists of layers of absorbent cotton, spread smoothly over flexible metal backs of varying size.

The material is easily obtained, and is so inexpensive as to warrant a fresh supply for every patient.

In all this, reference is of course made to the external electrode, which, in the treatment of the uterus and its appendages, is usually placed upon the abdomen. The internal electrodes consist mainly of a small metal bulb attached to a long insulated stem, for applications to such portions of the uterus as can be reached per vaginam; of metal probe electrodes, for intra-uterine applications; and of needles of varying size, for electro-puncture. It should ever be borne in mind that when the positive pole is applied to the interior of the uterus, the metal should be of some non-oxidizable metal, as platinum. In the electrolytic treatment of fibroids a good milliamperemeter is a necessity. The external electrode, whether of sculptor's clay or other material, is first placed upon the abdomen, and may be pressed upon and kept in position by the hands of the patient herself.

An insulated needle is now introduced into the tumor either through the vagina or through the abdominal walls, and the current gradually increased without interruption until the required strength is obtained, which may vary from one to two or three hundred milliampères. The duration of the séance may be from five to ten minutes, and even longer if the patient bears the operation well. Too much stress cannot be laid upon the necessity of an entire absence of any interruption of the current during the treatment. In trivial operations, where the tension is slight, this is not of such vital importance, but in the treatment of conditions where a very great strength of current is necessary, a shock would decidedly disturb a patient of even strong nerve, and inflict serious damage on many. No one would willingly do this, but there are so many possible disturbing factors to the steady working of the current, that from my personal knowledge of the condition in which physicians too frequently keep their electrical apparatus and appliances, these interruptions are liable to occur at any moment and when least expected or desired. It is to be doubted whether many patients would submit to a second trial after having received a shock from a current strength of two hundred milliampères.

While the treatment of fibroid tumors by electro-puncture is liable to be attended with more unpleasant results, it is no more efficient in many cases of uterine myomata than the more simple method of intra-uterine applications; and in our opinion the latter method should, as a rule, be attempted before resorting to puncture.

If, however, in any case of fibroid it is impossible to enter the cavity with our electrode, or when a sub-peritoneal tumor is so situated as to be beyond the effects of intra-uterine applications, in these emergencies puncture is of course the only choice. Punctures may be made either through the vagina or through the abdomen. The former method is generally preferred.

In the intra-uterine treatment of fibroids the strength of the current that may be used varies from 30 to 150 milliampères, and the negative pole, because of its superior absorptive properties, is to be preferred. In hemorrhagic cases the positive pole is indicated, and it cannot be too often repeated that, with this pole, platinum or some other non-oxidizable metal should always be used. In chronic cases the idea is, according to Apostoli, to destroy the mucous membrane and produce a healthy derivation.

The faradic current, which is so valuable in simple uterine engorgements following abortions, and perhaps in the earliest stages of metritis, becomes useless in the presence of parenchymatous metritis.

The chemical action of the galvanic current is alone serviceable in these cases. As in the treatment of fibroids, powerful currents are demanded, varying in strength from 50 to 150 milliampères. Some good form of rheostat should be used, and as the current is gradually increased and decreased the utmost care should be exercised to avoid shocks. The operation is not electrolysis proper, but more correctly a chemical galvano-cauterization. The choice of the intra-uterine pole will be determined by the symptoms in each individual case.

At the positive pole the acids and oxygen accumulate. This pole is therefore coagulating and hæmostatic, and is indicated in all forms of hemorrhages and abnormal discharges. Another advantage possessed by this pole in hemorrhagic conditions is due to the greater retractibility of the positive cicatrices, which tend to prevent a return of hemorrhages. At the negative pole alkalies accumulate, producing some of the effects of caustic potash. It is sometimes called the fluidifying pole, and is more especially indicated in the non-hemorrhagic forms of metritis.

It is especially valuable in old, atrophic, or indurated forms of chronic metritis, where the connective tissue has become hard, fibrous, and devoid of blood. Far more effectually than the positive pole, it excites the languid or perverted uterine circulation and restores the menstrual flow. The caution never to use with the positive pole, in intra-uterine applications, any steel or other oxidizable electrode, cannot be too strongly emphasized.

Platinum is to be preferred, and, although it is expensive, it never wears out. A cheaper form of electrode is made of carbon so thoroughly polished as to render it non-irritant, or of steel subjected to certain processes by hydrogen which render it non-oxidizable.

In time, however, both of these materials become roughened through the constant action of liberated oxygen.

Peri-uterine hæmatocele, uterine hyperplasia, and stenosis of the uterine canal, have also been successfully treated by the newer methods. Even salpingitis, through the depletion and drainage secured by electricity, has been decidedly benefited.

Cataphoresis.—By this is meant the introduction of medical substances into the body by means of the galvanic current. It is a method that has long been known, but it is only within the last few years that it has been largely attempted. Its application is exceeding simple. In using cocaine, for example, for local anæsthesia, it is only necessary to place upon the absorbent covering of the positive pole a five to ten per cent. solution, and, after the current has passed for a few moments, marked anæsthetic effects will be observed.

In order to secure exact dosage it is convenient to have a flat metallic electrode, preferably of platinum, upon which is fitted a piece of tissue paper or some other compact absorbent material. Upon this is placed drop by drop the solution of any drug to be used, and the electrode is then applied to the skin.

In this way the exact quantity of the drug is known. It is hardly necessary to exactly measure the strength of the current.

As a rule a sufficient guide is to use the current only up to the point of easy endurance. Other remedies that have been used in this way with more or less success are aconitia, strychnia, and helleborin.

The author has known cocaine to afford marked temporary relief in some cases of neuralgia, and in epilation it has enabled him to operate with little if any pain to the patient; but that there may be danger attending the use of the remedy in this way, admits of little doubt. A one per cent. solution of helleborin has been said to act even more satisfactorily than cocaine, producing deeper and more lasting, and accompanied by no constitutional, effects. The salts of lithium have been used for rheumatic and gouty swellings, and among mercurial remedies the imidosuccinate and bichloride of mercury are suggested. Before applying the medicated electrode to the skin it is a good plan to dissolve the oil-globules upon the surface by the application of ether. It is believed

that the "effects of the galvanic current upon nutrition are in part due to the cataphoric transfer of molecules of protoplasm and liquid from one cell to another, or from a cell to a capillary vessel in the path of the anodal stream; and since the diffusion takes place more readily and more quickly in direct proportion to the current strength, it behooves us to employ as many milliampères as feasible in our galvanization of the atrophied and paralyzed extremities of poliomyelitis, chronic neuritis, and peripheral nerve-trauma. Moreover, there would seem to be a possible advantage in the use of nutritive emollients in conjunction with the labile application of the anode to the atrophied member, just as they have been combined from time immemorial in the exercise of the aliptic art (massage)."

The use of iodine by cataphoresis has been attempted in cases of goitre, and good results have been claimed for it.

Bipolar Faradization.—By bipolar faradization is meant the localization of the faradic current by means of a single electrode, and the method is confined, for the most part, to the treatment of internal organs, such as the vagina, the uterus, the rectum, and the bladder.

Bipolar faradization, more perhaps than any other form of electrical treatment, necessitates a knowledge of the varied physiological and therapeutical properties of the induced currents of electricity. A current from a short, thick coil of wire (No. 21, say, in size, and but two or three hundred feet in length) will be of comparatively slight tension, but of so-called large quantity; while the current yielded by a long and thin coil is of little quantity but high tension, overcoming the greatest resistances with the utmost ease. When, therefore, it is desired to produce powerful mechanical effects in the external faradization of the body, a current of tension from a long and thin coil is needed; while to obtain these powerful effects in the faradization of internal organs, where the resistance is slight, a current of quantity from a short and thick coil is necessary. Let one become but once convinced by personal experience of the striking difference in the action of induced currents of quantity and tension on nerve and muscle, and he will hardly need the demonstration of clinical experience to convince him of their different therapeutical properties. The short, thick coil offers very little resistance to the passage of electricity, and so gives forth a current of little tension but large quantity.

When applied externally its appreciable influence is very slight. Its tension is so low that it overcomes with exceeding difficulty the resistance of the skin that must be encountered in all external applications.

The important practical point in connection with this current is the extraordinary increase in energy that is manifested when it is applied to parts within the body. When applied to the rectum, the vagina, or the uterus, not only are the contractions pronounced, in response to a current which is not strong enough to produce any observable effect when applied exterually, but they may easily become exceedingly painful. When applied, indeed, to these internal organs by the bipolar method, its extraordinary action on motor and sensory parts will hardly be credited without actual demonstration. It is the easiest thing in the world to demonstrate this fact unwittingly, to the injury of the patient and to the operator's mortification. This is what may very readily occur:—An intravaginal or intra-uterine application is being made with the current of tension. The patient complains of an uncomfortable sensation, which may or may not be due to the action of the current, and you exchange the current of great for one of lesser tension, which, according to all the experiences of external application, is infinitely weaker. Instantly a shock is occasioned, associated with the acutest pain and the most rigid contractions, that astonishes yourself and terrifies your patient.

The advantages of the induced current of quantity from the short, thick coil of wire, over the current of tension from the long, thin coil, lie almost wholly in the effects of their internal application, and especially by the bipolar method. This current is capable of exciting contractions of the involuntary muscular fibres of the uterus, of every degree of severity.

For this reason it is invaluable in cases of post-partum hemorrhage, and must, it seems to me, prove far superior to ergot for its suppression, since it acts instantaneously and with a force just sufficient to accomplish the object desired. Currents of tension, however, from very long and thin coils, while they overcome with great readiness the enormous resistance of the skin and produce effects of a most pronounced character, exert by no means the same influence over the contractions and sensibility of the vagina, uterus, rectum, or bladder. So tolerant, indeed, are the internal muscular organs of the body to the induced currents of tension, that it is frequently a question of how to obtain a current of sufficient power from the batteries in ordinary use. Batteries that have been long in use, and that are allowed to get out of order, while perhaps yielding a current of sufficient strength for localized applications externally, are insufficient for bipolar applications.

Even if at first the current is appreciably felt in the uterus, the sensitiveness soon subsides, although its strength may have been very much increased; and both physician and patient may be in doubt as to whether the current is being received at all. This phenomenon becomes promineutly apparent in hysterical cases with which is associated excessive hyperæsthesia of the abdomen, and it has been no uncommon thing in my observation to treat women with the current of tension for the relief of the most acute surface abdominal hyperæsthesia, and at the close of a single séance to find the abdomen insusceptible to any ordinary manipulation.

Far different is it with the current of quantity. Tolerance is not established, and what is painful in the beginning continues more or less painful throughout the treatment, and it frequently becomes necessary to decrease rather than increase the strength of the current. A No. 21 wire, with a length of five or six hundred feet, constitutes a satisfactory coil for currents of quantity; while No. 36 wire, with a length of three thousand feet and more, is necessary to obtain the best effects of current tension. Among comparatively new devices and suggestions connected with electrical apparatus and methods of application, may be mentioned the franklinic interrupted current, electrodes for eliminating polar effects, and the various arrangements which enable us to directly utilize the current from the street. The static induction current is obtained from any machine that generates static electricity. The static discharge in the form of sparks becomes dynamic, and closely allied, in the effect that it produces, to the ordinary induced or faradic currents of electricity.

The spark no longer directly affects the body of the patient, but occurs in some distant part of the circuit, thus obviating the shocks which are to some so disagreeable. There are two methods by which we obtain the static induction current: 1st, with the electrodes attached to the prime conductors either without or with the condensers; 2d, with the electrodes directly connected with the condensers. On account of its high electro-motive force, and the readiness with which it overcomes the resistance of the skin, this current is often of great value in alleviating pain. It seems to me, however, to be inferior to the galvanic current in this respect, and yet it does relieve, as does the faradic, in some cases where the galvanic has failed. The differential indications for the use of currents of quantity and tension are, however, too wide a subject to be discussed here. I will only say that I have not infrequently found that the static induction current has proven more efficacious for the relief of pain than the ordinary faradic current.

It is well known that what is called the faradic current of tension is far more efficacious in relieving pelvic pain than currents of quantity; and the static induction current is a current of but little quantity but enormous tension.

When we consider that its voltage runs up into the thousands, it is not difficult to accord to it, despite its lack of quantity, special physiological and therapeutical

properties. In the remarkable rapidity of its interruptions and alternations, also, the static or franklinic interrupted current is unique. While the average induction coil gives but a few hundred vibrations per second, it is claimed by physicists that the oscillations of each spark of the static current amount to many millions per second, and that these sparks follow each other at the rate of two hundred per second. The superiority, then, of the static induced current over the ordinary faradic in relieving pain is undoubtedly to be ascribed, first, to its superior tension; second, to the inconceivable rapidity of each spark-oscillation, amounting to many millions per second. It should, however, be borne in mind that the vastly improved coils now obtainable have greatly increased the anæsthetieal properties of the faradic current, and for the relief of uterine and ovarian pain these high-tension inductive currents are unsurpassed.

A. D. Rockwell.

EMBRYOS, HUMAN. AGE.—It has been quite generally accepted that the age of an embryo must be determined by the time of a certain cohabitation. In many cases it was attempted to locate the day exactly. After it had been shown that the ovum is extruded from the ovary at or before menstruation, it was then generally admitted that the egg could be fertilized at any point between the ovary and the uterus. The time required for the ovum to pass through the Fallopian tube was considered the time in which it was capable of being fertilized. According to the above, these conclusions are not based on a sound footing, because of the difficulty in obtaining accurate observations, and also because they do not agree with the results obtained from the lower animals. Both Coste and His have shown that the eggs of the hen are fertilized ten or more days after copulation, and the former has shown that the egg is no longer capable of fertilization after it has passed through the after-portion of the oviduct.

Impregnation is nearly always marked by a cessation of menstruation, and it now remains to be shown whether the fertilization takes place during the last menstrual period, or at the time of the first cessation; for it is known from post-mortem examinations that ovulation comes just before menstruation. Since it seems to be necessary to fertilize the egg just as it leaves the ovary, it is probable that impregnation takes place just before the menstrual period. To locate the menstrual period, from which to compute the age of an embryo, we must consult the following table, which is in great part copied from His.

Number.	Observer.	Length of embryo in millimetres.	Beginning of last period.	Last possible cohabitation.	Time of first lapsed period.	Day of abortion.	Time between Abortion and		Probable age of embryo.
							Last period.	First lapsed period.	
							Days.	Days.	Days.

* I have not full confidence in Stubenrauch's data. Some very apparent errors have been corrected. † Earliest cohabitation.

From a comparative standpoint we can easily determine the age of human embryos within four weeks. Counting from the last menstrual period, it is quite easy to see by the size of the embryo whether or not it is, say three or seven weeks old. The table shows that, by counting in this way, embryos of the same size may have a difference of four weeks in age (see Nos. 5, 11, 13, and 14). In these cases the age corresponds to the other cases, if from their time twenty-eight days are subtracted. This already indicates that, as a rule, fertilization of the ovum takes place during the ovulation which precedes the first menstruation which has lapsed. After Reichert had shown that menstruation is only a method of clearing out the uterus after an ovulation, and after Leopold had shown that the mucous membrane of the uterus undergoes histological changes before ovulation, it is fair to assume that the latter changes are only preparatory to the reception of the ovum, and that when the unfertilized ovum reaches the uterus, menstruation is only a method of reducing the uterus to its former condition.

Only in four of the cases is it necessary to compute the age of the embryo from the last menstrual period, and it is not fair to assume that just these four embryos have grown too rapidly. All the rest must have twenty-eight days subtracted from the time in order to make them correspond with the above four. These are the main reasons for assuming that the fertilization of the egg takes place just before the first menstrual period which lapsed. It may be that a great many fertilizations take place during the last menstrual period, but that when menstruation has once begun, the activity of the uterus destroys the ovum, and that, as a rule, only those are preserved in which menstruation does not follow the last ovulation. At least the embryological evidence speaks for this, and at present embryologists make their specimens correspond to one another when they reckon their ages from the last menstrual period, minus twenty-eight days.

The table shows, in addition, that in certain pregnancies the first cohabitation followed the last menstrual period. It cannot be that in these cases the ovum of the last period could have been fertilized, for it is quite certain the ovum loses its power of being fertilized shortly after it leaves the Graafian follicle. In case No. 9 (B B), the first cohabitation of a newly married woman took place on April 4th, say about five days after the last menstrual period; and the woman ceased menstruating at once, probably on account of the fertilization of the ovum of the following ovulation. If all the cases of

newly married women in which there was an early pregnancy were collected, it would, no doubt, be shown that in many of the cases the women did not menstruate at all after marriage. At present, although not being a practitioner, I know of four such cases. His has tabulated cases given by Harter, in which the first copulation, the last menstrual period, and the date of birth of the child are given. In all of these cases the age of the fœtus is from two hundred and seventy to two hundred and eighty days, if the beginning of pregnancy is reckoned from the beginning of the first period which has lapsed. If the beginning of pregnancy is placed at the first cohabitation, the age of the fœtuses varies fully a month according to the time of the cohabitation; if the time which has elapsed between the cohabitation and the first menstruation which lapsed is subtracted from the duration of the pregnancy, then the lengths of the pregnancies are practically alike. Assuming that the lengths of pregnancies should be about the same, it makes it highly probable that fertilization takes place at the time of the first menstrual period which has lapsed rather than at the time of cohabitation.

In several of the cases given in the table, the last cohabitation took place several weeks before the cessation of menstruation, showing that the vitality of the spermatozoa within the female organs lasts for at least a few weeks. It is probable, however, that the spermatozoa cannot live in the Fallopian tubes or uterus for over a month, because authentic posthumous births always take place within two hundred and eighty days after the husband's death.

The general conclusions formulated by Professor His, and accepted by embryologists, are as follows:

1. The beginning of development is the time of impregnation, *i.e.*, at that moment when the spermatozoon enters the ovum.

2. The time the egg leaves the ovary is marked by menstruation, but it is not necessary for the Graafian vesicle to rupture during menstruation; it may take place two or three days before or even during the hemorrhage.

3. The egg is not capable of being fertilized at any point from the ovary to the uterus, but only shortly after it has left the ovary; as a rule, as it is entering the Fallopian tube.

4. The spermatozoa which have entered the female sexual organs must await the ovum in the upper part of the Fallopian tube, and can retain their vitality here several days, or possibly several weeks. The time of cohabitation is, therefore, not directly related to the age of the embryo.

5. The age of the embryo is to be counted from the beginning of the first menstrual period which has lapsed, although it is possible to have a menstruation after fertilization of the ovum.

6. The age of an embryo can be expressed by the following formula: $A = M + X - 28 \times 3$, in which M is the beginning of the last period, X the time which has elapsed before the abortion, and the 3 the time between ovulation and menstruation.

There is no reason why the gynecologist should not add his share in determining the age of embryos. Any physician would add greatly to the subject if he would tabulate all cases in his practice after the plan of the above table. It would not be necessary to confine himself to young embryos alone, but he might include children at full term; especially those of newly married women would be valuable. Moreover, if the young specimens were carefully preserved, he could do a great work hand in hand with the embryologist.

Preservation.—The human embryos which come into the hands of the embryologists are nearly altogether worthless for careful study, due to careless preservation. Of fifty embryos less than six weeks old, which have come into the writer's hands during the last few years, only four have proved to be valuable, and these came from two physicians. The main reason why specimens are destroyed, in nearly all cases, is that the ovum is placed in very dilute alcohol, and in so doing it is also handled very roughly. Yet poor specimens are better than none at all, and in all cases all ova should be preserved, even if there is but little hope for a good specimen. *The best and most convenient method of preserving young embryos is to place the unopened ovum, with the least possible handling, in a large quantity of very strong alcohol.* The alcohol of druggists is in no case too strong, and, according to my experience, is as a rule too weak. Often the ovum is wrapped in a towel and then placed in a small quantity of alcohol and water. This may be a method of preserving museum specimens, but it practically ruins every embryo which is preserved in this way. When an ovum is placed in, say four ounces of strong alcohol, the water of the ovum dilutes the alcohol to a proper strength.

Those physicians who have the proper opportunities should place the specimen as soon as possible, and without opening the ovum, in seventy per cent. alcohol, *i.e.*, absolute alcohol reduced by volume to seventy per cent. At the end of a day or two it should be placed in fresh alcohol of the same strength.

A second convenient method is to place a specimen in quite a large quantity of Müller's fluid, to be changed once or twice during the first few days, after which it may be preserved in the same fluid indefinitely. The embryo is fully hardened in about a month, and then it can be washed in water for a day or two, after which it is to be preserved in seventy per cent. alcohol.

Ten per cent. nitric acid is a convenient and a most excellent method. The ovum is to be placed in four or six ounces of a ten per cent. solution and opened while in the fluid, care being taken not to injure the embryo. According to its size (if not over an inch long), it should remain in the acid for from thirty minutes to two hours. At the end of this time it is to be placed in seventy per cent. alcohol.

Another excellent method is to employ saturated aqueous corrosive sublimate. The specimen is to be treated as in the ten per cent. HNO_3, only it is to remain in the sublimate longer. These specimens are then to be preserved in seventy per cent. alcohol.

There are many other methods, but if any of the above are employed there will be a sufficient supply of material to aid the study of human embryology. It is really wonderful to see what progress has been made in this study when we consider how difficult it is to obtain good material. Some of the most important discoveries have been made in the careful study of a few well-preserved human embryos, as a glance at the many papers of His and at the excellent text-book of Minot will show.

A great work is done when the specimens are once obtained, but in order to make it complete they must be placed in the hands of a specialist, who can devote all his energies as well as all the additional necessary expense to these—the most precious of embryological specimens.

Franklin P. Mall.

EMOTIONS, THE PHYSIOLOGICAL AND PSYCHO-PHYSICAL BASIS OF THE. The practitioner of medicine is not universally expected to command a minute or special knowledge of psychology, but he may, and should be, familiar with certain intimate anastomoses of this subject and physiology. At a time when so-called psychological healing offers active competition to medicine in certain quarters, it behooves the physician to understand and to be able, if need arises, to formulate the conditions of psychical influence upon the body. On the other hand, men who are daily brought face to face with abnormalities of psychical function in connection with diseased bodies, and whose attitude is essentially critical and practical, might exercise a most wholesome influence upon the development of that new psychology which lays claims to recognition as a natural science.

The scholastic and convenient tradition which divides psychical manifestations into cognitions, volitions, and feeling, permits us to single out a class of so-called mental manifestations, which are conceived to be determined by a form of the receptivities of mind known as the susceptibilities. The most careful writers have discovered

in this group of "faculties" a perennial source of dispute and ambiguity.

Older psychologists conceived of feeling as obscure or implicate thought, or as impotent or unexpressed impulse or will.

Hoeffding defines feeling as "that in our inward states which cannot by any possibility become an element of a percept or an image;" as "an inner illumination which falls on the stream of sensations and ideas." Both these expressions indicate the difficulty involved in isolating feelings, the one being negative, the other an illustration. Sibbern notices that feelings and will have this in common, that in both "the ideas involved have a personal hold and effect, so that we yield ourselves up to them and are incited to act and strive for their realization." Recognizing the futility of the distinctions usually made, James has boldly used feeling as synonymous with the word psychosis or subjective state, and made no attempt to distinguish it from thought. The emotions (German *Effecte*) are described as a bubbling up of feeling which may greatly influence the course of cognitions and volitions, or temporarily inhibit or stimulate them. If emotions be strictly limited to feelings with psychical (cognitive) occasion or accompaniment, much ambiguity may be avoided, but it would still be necessary to insist on the essential similarity of these feelings to others with simple sensational basis. The following classification may prove convenient:

I. *Feelings.*	Sensations.	Sense gratification and pain.	General or total feelings.
II. *Occasions.*	Normal (moderate) sensory stimuli.	Super-normal stimuli, with tendency to irradiate.	Diffuse (somatic, especially "total") stimuli.

Emotions.	Impulses.	Sentiment.	Disposition.
Somatic changes occasioned or accompanied by cortical activity.	Reflexes excited by somatic and cortical activity.	Persistent cortical changes.	Reactions of cortical residua on new data of consciousness.

This series of subjective states is not to be regarded as arbitrary, but capable of the most far-reaching interpenetrations. Of course it may be claimed that there is a great gap between sensation, or even bodily pain and pleasure, and the emotions which depend chiefly upon data of a higher intellectual character. Between these two groups is another, which seems, in part at least, to bridge over the interval, the total or general feelings.

Sensations, as the most direct responses of the consciousness to external irritations in which the bodily participation is more direct than in the subsequent processes (perception, etc.), afford the simplest data of consciousness. Even in this case, however, the nature of the response varies with the organ in respect to the amount of subjective participation. Thus, sensations are excentrically projected or externalized; the former in the case of tactile, gustatory, thermic, and algesic senses; the latter in the case of special senses—visual, auditory, and olfactory.

That this is not a primitive difference, but is developed through associations of several senses, is proven by such facts as that when a blind person is suddenly given sight, the external world seems to touch the eye, *i.e.*, is excentrically projected rather than externalized. That externalization is possible to the tactile sense or "muscular sense" is shown by hyperexcentric reference of sensations of double contact, as when the blind man seems to feel an object at the end of his cane, or the surgeon's sensation is transferred to the end of his probe. We may dismiss, as beyond our limits, the three sciences —optics, acoustics, haptics (the skin and muscular sensations)—and there still remains a set of sensations which may be conveniently grouped as general sensations, which bring us into closest relations with the lower special senses, olfaction and taste, and the diffuse sensations on one hand, and subemotional processes, like elation, ennui, and depression, where total sensations and rudimentary feelings fuse.

It must not be forgotten that pain and sense gratification are strong elements in the emotions and require a careful examination. Hoeffding says "feeling stands out plainly, as an element different from the actual sensation, in certain experiences, which prove that the pain caused by an excitation takes longer to be produced than the actual sensation, and that sensation may arise without the corresponding feeling, and *vice versâ*." Richet says "pain without memory and without radiation would be no pain at all." Often an interval of one or two seconds may elapse after the sensation is perceived before pain appears. These cases, so often quoted as proving the distinct nature of pain, are in one respect fallacious. When a nerve-fibre is penetrated by a pin the pain is nearly, if not quite, as promptly felt as the touch. When the finger is struck by a hammer the pain is frequently long delayed. But the acme of pain in that case is due to a reactionary process in the tissues, notably the vascular contractions, etc. There may be several oscillations of pain and a set of summations of a curious character. It is even possible, by bringing to bear counter-irritants, to preclude these after-effects and mitigate the pain, as by rubbing or pinching the part.

In the case of a burn the conductivity of the tissues and vascular responses are even more evident, and such attempts to differentiate pain from sensation as a modality of feeling are futile. The fact that there may be analgesia without anæsthesia, and *vice versâ*, is tentatively explained by the recent suggestion, that thermic and painful sensations find their way to the cortex through the gray matter of the cord instead of the fibrous columns, and affords us added data for the generalization for which we are now ready, viz.: Feeling is always composed of two sets of factors; first, a sensational, and second, a cognitive or intuitional element. The sensations which directly participate in feeling are non-localized (general or total sensations), or are so acute as to irradiate, and thus ally themselves with total sensations. The cognitions or intuitions are primarily such as identify the subjective state with the empirical ego. The association of reflexes and instinctive responses converts the feeling into an impulse which is usually embodied in the so-called emotion.

James identifies instincts and emotions as two forms of impulse, in this usage betraying German influence. He says that the class of emotional is rather larger than that of instinctive impulses. Its stimuli are more numerous, and its expressions are more internal and delicate, and often less practical. The physiological plan and essence of the two classes of impulse is the same. This identification of the expression of the emotion with the psychical element (feeling) seems illogical, inexpedient. Instincts may have an emotional origin, or may be of the nature of impulse deprived of its psychical element; but pure instinct is not emotional, though emotions may be awakened by a resistance to the gratification of the instinct. An impulse stands on a present or historical basis.

With this difference in distribution, the theory of emotions proposed by Professors Lange and James goes far to place the emotions on a plane of scientific research. As expressed by the last named, this theory is about as follows: Bodily changes follow directly the perception of the exciting fact, and our feeling of the same changes as they occur is the emotion. Objects excite bodily changes by a pre-organized mechanism, and these changes are so indefinitely numerous and so subtle that the entire organism may be called a sounding-board, which every change of consciousness, however slight, may make reverberate. Everyone of the bodily changes is felt acutely or obscurely the moment it occurs.

James says: "If we fancy some strong emotion, and then try to abstract from our consciousness of it all the feelings of bodily symptoms, we find we have nothing

left," . . . "a cold and neutral state of intellectual perception is all that remains." "The more closely I scrutinize my states, the more persuaded I become that whatever moods, affections, and passions I have are in very truth constituted by, and made up of, those bodily changes which we ordinarily call their expression or consequence." These quotations serve at least to emphasize the importance of the corporeal element, however much they ignore the cognitive element. The natural and logical criticism is that the *effect on consciousness*, which is all we get out of feeling, is wellnigh overlooked.

Emotion consists (1) of general sensations of total, organic, or irradiating varieties which have in common a lack of localization and, as a result of associational laws, are amalgamated more or less closely with the empirical ego; (2) of more or less explicate or implicate cognitions (perceptions, intuitions) of the relation between the cause of the sensation and our well-being; (3) the emotion is more or less closely attached to various impulsive expressions which tend in various ways to intensify the two preceding. More in detail: The sensations are produced in most cases by vaso-motor changes which, in turn, produce "total sensations," usually entirely unlocalized and not necessarily distinguished apart from the feeling. Such sensations may be recognized, and to some extent analyzed, by practice. They precede the emotion proper and compose its sensational element. When one lies half asleep in the morning and a loud report startles him, the sudden surging of the blood to the periphery produces a familiar but indescribable sensation, which may include tingling at the finger-tips, a curious twinge in the axials, a suffocating sensation in the chest, as more specific accompaniments. Then a flash of fancy depicts the burglar in the kitchen and a scene of bloodshed, danger to self, and the like; now perhaps a strange "gone" feeling in the abdomen, and helpless atonic condition of muscles follow; then impulse dominates, and the tendency to spring to the defensive arises; all this before judgment announced that the cook has slammed the range door. Granting that the illustration has served to indicate the meaning of the statement above, it need require but brief experiment and self-observation to show that vaso-motor and organic changes always accompany and afford a sensational basis for feelings. A just analysis will not neglect the subjective processes in construing the physical. Stripped of the sensations above referred to, and the instincts and impulses associated with them, the residuum is still not to be passed over. "A feelingless cognition that certain circumstances are deplorable," or otherwise, may be, and generally is, but the first step in a series of judgments or representations out of which spring the involuntary acts which are the really important results of emotion. The sensational element is that which represents the general, though subtle, bodily effect of the stimulus (be it physical or psychical), while it serves to awaken within us the empirical ego (the sum of our purely subjective bodily reactions on consciousness), which gives point or poignancy to the following psychical processes and links self with phenomena, awakening the participation of the soul in the states of the body, or of other beings, which otherwise might concern us only as do phenomena in Mars. It is then no mere figure which localizes the emotions in the heart or bowels, but a statement of sober physiological truth. A heartless man is one whose intellectual appreciation of the results of an act does not awaken sympathetic thrills in his physical being adequate to quicken in him a participatory or sympathetic state. Such a condition may be acquired by habit or produced by heredity. Practically, we are first interested to study the physical substrata conditioning the emotional temperament and its expressions.

The sensational elements in emotion are, first, pains and sense gratifications; second, obscure organic and total sensations which are not usually perceived as such, but are interpreted as part of the feeling; third, reproduced pains or gratifications always followed or accompanied by total sensations; fourth, representations which awaken by association either reproduced pains and gratifications which, in turn, give rise to total sensations, or the latter without the former; fifth, instincts, which obey laws of association whose rational explanation lies in the development or phylogenetic history.

Pain and sense gratification are more difficult to construe, because more direct and simple than the others named. So long as pain, etc., were regarded as simply exaggerated forms of ordinary sensation the problem was insoluble. That this is not the case is suggested by the fact that they pursue other courses in the cord, and are associated more closely with thermic sensations. If a small area of the skin is isolated it is found that tickling with a feather is interpreted as warmth, and a thrust with a needle cannot be distinguished from heat. In other words, if the local signs by which position is recognized are excluded, the differences break down. It may be noted that general changes in temperature states are closely connected with the general feelings, as witness a shudder or the cold chills of fear, and the glow of pleasure. Briefly stated, the peculiarity of pain and intense gratification of sense which adapt them to become sources of feeling, is their diffusive (irradiative) character. If the current suggestion that algesic stimuli pass by conduction through the gray matter of the cord be substantiated, a much closer connection with the visceral centres than hitherto suggested may be postulated, and the thrill of pain can be readily interpreted as the sympathetic contraction wave passing throughout the vascular system. The evidence for the existence of adequate vaso-motor causes of the sensational element in emotion is largely subjective, but those familiar with nervous diseases will not lack for evidence that variations in circulation are powerful factors in emotional disturbance. Shame is an emotion quite independent at times from any judgment of adequate occasion for chagrin. It is very closely connected with peripheral vascular changes. In anæmic or neurotic persons the flush may come without any external exciting cause, and yet frequently produces all the subjective effects of shame. Not very infrequently this symptom becomes intolerable and almost alone drives one from society. Still more frequently psychical reflexes become associated with it and enhance its power. Fear, which originates in a shock or contraction wave of the vascular system, bringing a whole series of visceral and secretory changes in its wake, illustrates the possibility of separating the sensational from the cognitive element. Dreams often afford instances of all the physical manifestations of fear, with no adequate cognitive process. The writer has dreamed of being the actor in a play in which fear of impending danger entered, and, in his capacity as actor, felt fear (sensational); while in his capacity of critic he, at the same time, observed the entire inadequacy of the supposed occasions of fear.

Lange says: "No one has ever thought of separating the emotion produced by an unusually loud sound from the true inward affections. No one hesitates to call it a sort of fright, and it shows the ordinary signs of fright. And yet it is by no means combined with the idea of danger, or in any way occasioned by associations, memories, or other mental processes. The phenomena of fright follow the noise immediately, without a trace of spiritual fear. Many men can never grow used to standing near a cannon when it is fired off, although they perfectly know that there is danger neither for themselves nor for others—the bare sound is too much for them." One who has walked over a railroad trestle by night and narrowly escaped a fatal plunge by observing just in time the absence of a tie, will be able to recall the peculiar series of organic sensations involved. The thrill of vaso-motor disturbance pervading the body—the twitch of the radial artery—the pain in the sternal region—the suffocating sensation in the breast and lump in the throat—and, finally, the "gone" sensation in the abdomen somewhat resembling a sensation of cold, and due in all probability to vaso-constrictor reactions in the visceral vessels—these, and many more, illustrate the bodily effects which may wholly precede the apprehension of danger, and may be enhanced by a variety of imagination pictures, and may express themselves in impulsive gasps and gestures. It is not necessary to call attention to the fact that mental

images may be almost equally effective with the actual external irritations in producing the sensational responses of emotions. Before passing from the direct sensational elements, however, it may be noticed that those senses which externalize their data (vision, hearing, etc.) have special powers over the emotions which may in part be explained by a sort of central (bulbar ?) irradiation. Simple colors and musical sounds produce a vague and feeble pleasure unworthy to be called emotional, but similar to the normal subjectivity of nervous action ; but a symphony or aurora plays on the sensitive organism like a harp. The writer, without musical tastes or education, confesses to the tumult of indescribable sensations produced by Wagner or Beethoven. Flushes of cold and heat ; tinglings and palpitations local and general ; gusts and torrents in the blood ; creeping, swelling, scintillation of the skin ; giddiness and elation—these and indescribable "all-over" sensations are easily separable from intellectual appreciation, which may even be absent ; and one may be a wondering spectator observing the irrational gyrations of his own sense to tintinnabulating stimuli upon which judgment turns the cold shoulder. Another class afforded by the tickling and shuddering or irradiation sensations proper, further illustrate the necessity of diffusion in emotional sensation. The slight sensations of tickling, aided by subjective modifications, extend in most varied and irresistible sensations over the whole body. Its emotional character is almost wholly apart from the intellectual element. The shudder and chill which spring from a gritting sound or the velvety touch of a peach, imply in addition considerable instinctive elements.

The effect of instinct is powerful in the emotions generally. The faintness at sight of blood may be entirely apart from apprehension. The universal creepiness inspired by the approach of a harmless snake or the proximity to a precipice, are illustrations of a form of sensation obviously highly developed in animals (witness the rising hair of the new-born kitten at the odor of a dog). The sight of many small animals, pets, or children, produces a marked thrill in most children, often accompanied by curious sensations at the root of the teeth (analogous to the sensation sometimes felt with surcharged bladder), and accompanied by strong impulse to squeeze or hug the animal, to contract the muscles of the jaws, arms, etc.

These are often very powerful sensations, and productive of almost violent impulses. They are analogous to certain sexual instincts (perverted in gynophagia, etc.), but are quite distinct from them.

The impulses of emotion have received careful study, and only too often have been identified as part of the feeling. If it were desired to analyze emotion as of threefold character, thus : sensation, cognition, impulse, there could be no serious objection, except that impulse does not always require consciousness of its occasion as emotion must. Strong evidence as to the nature of emotion is afforded by the fact that imitation of the expressions of emotion reflexly awaken the emotion, while vigorous repression of these impulses quickly obliterate it. Distraction of the attention may check the tempest rising in a child's bosom which, once overflowing, could only find relief in exhaustion.

Many persons who are not suspected of neurotic disease, have a transitory mania which exhibits itself in paroxysms of fury as blind and unreasonable as those of a maniac, and which may be occasioned by trivial circumstances. The fact that impulsive responses to emotional excitation have this reflex power is a significant one in the treatment of nervous disease Bucke's description of nervous dyspepsia may find a place here. "All physicians who have been much engaged in general practice have seen cases of dyspepsia in which constant low spirits and occasional attacks of terror rendered the patient's condition pitiable in the extreme. I have observed these cases often, and have watched them closely, and I have never seen greater suffering of any kind than I have witnessed during these attacks. . . . Thus a man is suffering from what we call nervous dyspepsia. Some day, we will suppose in the middle of the afternoon, without any warning or visible cause, one of these attacks of terror comes on. The first thing the man feels is great, but vague, discomfort. Then he notices that his heart is beating much too violently. At the same time shocks or flashes, as of electrical discharges, so violent as to be almost painful, pass one after another through his body and limbs. Then in a few minutes he falls into a condition of the most intense fear. He is not afraid of anything ; he is simply afraid. His mind is perfectly clear. He looks for a cause of his wretched condition, but sees none. Presently his terror is such that he trembles violently and utters low moans, and at this stage there are no tears in his eyes, though his suffering is intense. When the climax of the attack is reached and passed, there is copious flow of tears, or else a mental condition in which the person weeps upon the least provocation. At this stage a large quantity of pale urine is passed. Then the heart's action again becomes normal and the attack passes off." It is not the purpose of this article to suggest remedial or obviating procedure, but it is obvious that the vaso-motor conditions in hypochondria and nervous acme of all kinds acquire new significance in this connection.

Another group of phenomena connected with emotional excitement has recently been adverted to.

In a paper before the International Congress of Experimental Physiology, session of 1892, Professor Hugo Münsterberg details the results of experiments, showing that the emotional states react differently on the extensor and flexor systems of skeletal muscles. After having for some time practised moving an index on a scale ten or twenty centimetres centripetally and centrifugally, until the distance could be quite accurately estimated with closed eyes, he tried the same experiment while experiencing pleasurable and painful emotions. The results are interesting. Purely physical variations, such as would be expected *a priori*, are seen in the under-estimation of the distance in dull or serious moods, and over-estimation when excited or amused. But psychical variations appear when they would hardly have been expected. Thus in unpleasurable emotions the extensor motions are too small, while flexor motions are too large, and during pleasurable emotions the flexor motions are too small and the extensor motions too large. The author does not hesitate to found on this observation the theory, that it is not simply true that painful emotions produce flexor motions and pleasurable emotions extensor motions, but that the psycho-physical effect of the reflexly produced extension and flexion is precisely what we term pleasure or painful emotion. A farther generalization is that extension must always, from the biological stand-point, occur with serviceable, and flexion with harmful, irritations.

Even the infusoria exhibit the same tendency. This lies at one extreme, while at the other the pleasurable emotion of assent is but an associated reproduction of earlier extensor motions, and *vice versâ*. Pain and pleasurable sensations acquire emotional value only through the aid of associated muscle sensations, *i.e.*, such as form the foundation of our empirical ego.

These suggestions are expressed in a somewhat different form in Tuke's well-known text-book. "By acting chiefly on the flexor muscles, fear causes the general bending or curving of the frame; while courage contracts the extensors, and produces expansion and height."

"The opposite muscular states of contraction or tension and relaxation, alike find illustration in the emotion of terror, for with the signs of the former already mentioned, and the stare of the eye, are combined the relaxation of the masseters, the sphincters, and the processes of organic life." "Calmness—a placid condition of the feelings generally—is marked by a gentle contraction of the muscles, indicative of repose, but at the same time of latent power—by the countenance free from furrows, but not relaxed into weakness. Anger or rage contracts the masseters, inflates the nostrils, furrows the forehead, and exposes and rolls the eye-

balls, clenches the fist, and induces a violent action and more or less rigidity of the muscles generally."

"As all movements have for their great end the preservation as well as the enjoyment of the individual, and as contraction and relaxation take place primarily to attain this end, a general expansiveness of expression and gesture is allied with all the emotions which are excited by impressions (or generated by ideas) of a beneficent character; while a general exclusiveness or contraction of features is allied with emotions excited by maleficent expressions; the object of one class of movements being to court and receive, and of the other to avoid and reject." "Pleasurable and painful sensations from without determine, then, the form which the muscles called into action assume; the purpose being to protect the organs. Similar muscular changes arise from the emotions, according as they are pleasurable or painful, in consequence of the harmony between mental and bodily acts."

The existence of impulses of the most recondite and adaptive sorts need not be denied, nor can it be doubted that these reflexly contribute to the emotional element. It must be urged, however, that emotion, strictly speaking, is subjective and must not be identified with its bodily occasions or results. The practical problem is to acquire control over the conditions.

The transition from emotion to sentiment is imperceptible. Joy and sorrow are sentiments growing out of pleasure and displeasure, and these have their counterparts in sense gratification. Conjugal love is the sentiment of which passion is the emotion, for which erotic excitement may afford one sensational basis.

The rhythmical flux of the feelings is explained by physiological oscillations. In the morning, when the current of life is full, emotions are not easily awakened. A morning audience is not a responsive or emotional one. The processes of nutrition exert a powerful effect. Physiological acme, like puberty, and the climacteric, predispose to emotions. The early development of the sensational element of emotion and its preponderance in the lower animals has been thought to imply that feelings are prior to cognitions. A more just analysis recognizes the psychical element of emotion as essentially intellectual, and abandons the attempt to secure a serial relation of the "faculties." An interesting and important field is thus open to the practising physician in the minute study of the pathology and physiology of emotions.

C. L. Herrick.

EPIDEMIOLOGY is the science of epidemics. It is therefore chiefly concerned with the distribution of disease, although it necessarily deals also largely with questions of ætiology (*cf.* Ætiology). The distinctive feature of an epidemic is the sudden and temporary appearance of a disease in a considerable number of persons in a community at the same, or nearly the same, time. The epidemical diseases are naturally, therefore, chiefly, if not wholly, extrinsic or environmental diseases. We cannot well think of intrinsic disease appearing simultaneously in large numbers of people. The explanation of epidemics was formerly simple, although really obscure. The commonest causes assigned were those described as "meteorologic" or "telluric." Exactly what these meant no one knew. "Emanations from the soil," "atmospheric conditions," and the like were the high-sounding paraphrases which have not yet wholly lost their force.

It is only within the last half-century that a more comprehensible set of causes has been introduced, and that the scientific study of the distribution of disease has become a possibility. With the establishment of the doctrine of *contagia viva* the subject of epidemiology became a part of general biology, and the distribution of disease began to be studied as the distribution of plants and animals had long been studied. Contagion and infection became easily interchangeable terms, contagion being only one method of infection.

At the present time we may safely assume the doctrine of a *contagium vivum* at the bottom of most epidemics, although in the last analysis it will be safer to assume the cause as toxic or toxicogenic. A poisoned well might easily produce an epidemic of arsenical poisoning. A car-load of trichinous pigs might as easily produce an epidemic of trichinosis in a community. An infected water-supply or milk-supply may produce an epidemic of typhoid fever. In all of these cases the ultimate assault upon the cells or the protoplasm of the body may be toxic in character, for while the trichinæ are lodged in the muscle, and the bacillus of typhoid fever may multiply in the intestine or in the blood or the tissues, the chief damage is done, in all probability, by substances produced by the invader which are essentially toxic. It is a significant commentary upon the dependence of definition upon knowledge and upon the value of a rational ætiology, that epidemics due to poisoning are seldom so called, being known rather as "cases," while epidemics whose origin is unknown, or not generally understood, are still called "epidemics," and popularly attributed to vague or supernatural causes.

If we allow that what are thus called epidemics are, in reality, due to living organisms such as the spirillum of Asiatic cholera or the bacillus of typhoid fever (and at present the evidence of ætiology certainly lends very strong support to this view), then we have in epidemiology simply to inquire—How may the organisms of infectious or epidemic diseases be so disseminated as to attack simultaneously a number of persons and thus generate an epidemic? Obviously food and drink afford convenient vehicles for the introduction into the alimentary canal of all kinds of particles, not excepting those which may act as the germs of disease. The atmosphere also may contain these minute particles, and, during the act of respiration, deposit them upon the pharyngeal or pulmonary mucous membranes. But even when so introduced into the alimentary or pulmonary passages the germs of disease may conceivably do no damage. They may find their environment unfavorable, or they may be destroyed by the digestive juices, or having penetrated into the body proper they may be captured by phagocytes, or killed by the defensive substances of the tissues. As a matter of fact we find in all epidemics some striking examples of apparent insusceptibility and exemption from attack, as well as cases affected in very different degrees, some lightly some severely.

These facts are usually explained by the doctrine of "predisposition." A in an epidemic suffers severely; B is entirely exempt, and C has only a "mild attack." It is usual to say that A was in a peculiarly "susceptible" condition, while B was not at all "susceptible," and C only slightly so. Theoretically this condition of things might easily have existed and each have received the same quantity of virus. Moreover, clinical experience strongly confirms this view, for in epidemics in general, and in those of typhoid fever in particular, it is the obviously weak or overburdened who most readily succumb to infection. But there is another possibility to be kept in view. The amount of the dose may have something to with the matter, and in this direction we are still very much in the dark.

It is now generally admitted by epidemiologists that there must be an exciting cause acting upon a community before an epidemic can arise. Even Pettenkofer has referred to this cause, in his latest publication upon cholera (see *The Lancet*, 1892), as very likely an organism, but something properly designated as x. The individual condition of susceptibility or immunity he designates as z. Most epidemiologists of to-day regard these two factors as sufficient to determine the question of the disease. But not so Pettenkofer, who adds to these an intermediate requirement, viz., *condition of locality*, which he designates as y. While insisting upon this, Pettenkofer urges that those who omit his y are destitute of epidemiological experience, and by virtue of their inexperience with epidemics easily become mere "contagionists." It is not easy to discover the evidence upon which Pettenkofer bases his claim for the importance of local conditions in the distribution of infectious disease. Those who are familiar with the works of Budd on typhoid fever will not readily accept the views of Pettenkofer,

and the doctrine of parsimony in logic will not allow us at present to require any other factors for disease than the fortuitous concurrence and combination of his *x* and his *z*.

It is uncertain to what extent the air is a carrier of disease, but the tendency of recent inquiries is to diminish rather than increase its importance. It is now generally held, upon the evidence of bacteriology, that the expired air is germ-free, so that this possible avenue, once regarded as important, and popularly still so regarded, is excluded. With pulmonary tuberculosis, diphtheria, and pneumonia, the sputum, when dried and pulverized, may act as the vehicle of disease driven by the air, but it is not yet accurately known to what extent the germs survive, or for how long, under natural conditions. With the exanthemata, particularly small-pox, scarlet fever, measles, and the like, there is every reason to believe that the disease is often disseminated through the air by means of infected epidermal scales driven about. In the diarrhœal diseases, on the other hand, it is apparently the bowel discharges (and only rarely the urine) which contain and convey the infection. Asiatic cholera and typhoid fever are apparently conveyed chiefly, if not exclusively, in this way. To provoke an epidemic of these diseases it is apparently only necessary to contaminate food or drink with (rather fresh) fecal material. Very numerous cases are on record of the dissemination of typhoid fever by infected milk and infected drinking-water, and the same facts are probably true of cholera. Dr. Budd long ago proved that the former disease is common among washerwomen, whose duty it is to wash infected linen soiled with the discharges of typhoid-fever patients, and there is an increasing quantity of evidence that milkmen and others suffering from incipient or walking typhoid may infect the milk which they sell by carelessness in cleaning their hands after defecation. One of the most instructive epidemics ever traced was that at Caterham, England, in February, 1879, where a small quantity of the fecal discharges of one workman, apparently in the incipient stages of typhoid fever, contaminated an otherwise pure water-supply, and led to 352 cases and 21 deaths from this disease. The low fatality may have been due to the enormous dilution of the virus.

If by food we may understand broadly food and drink, then it is probably true that the principal vehicles for distribution of the seeds of disease are *food and fingers*. In the diarrhœal diseases this is certainly true, and it will very likely be found hereafter to be equally true of other infectious diseases, although for diseases of the throat and lungs, such as diphtheria and tuberculosis, kissing may hereafter be found to be the most effective agent of distribution. Of contagion in the popular sense, namely, the "taking" of a disease directly, from mere contact or touching, there is probably no real example, except in kissing or venereal disease; but the hand must certainly be regarded as the ready carrier of the germs of disease to the mouth, so that "contagion" may readily result in infection. It ought to be more widely understood than it is that unclean hands may infect food, and that although contagion in the old sense plays a small part, the co-operation of fingers and food may make a very "short cut" for the distribution of disease. The author has seen epidemics of typhoid fever plainly due to secondary infection of this kind among unclean people, whose families prepare and serve their own food. These cases are more obscure, but not less instructive than those in which a public supply, such as water or milk, shared in common by many, has become infected. It must not be forgotten that if the modern views of the ætiology of contagious disease are correct, there can be no more real mystery in the genesis of epidemics and the distribution of disease than in the genesis of nations or forests and the distribution of plants and animals.

William T. Sedgwick.

EPILEPTICS, THE CARE OF. The care of epileptics really includes their medical treatment as well as all other kinds of help extended to them. But medical care has been given them, such as it is, for some thousands of years, and yet without adding much to the happiness of individuals under treatment, or accumulating much evidence of positive value concerning medication in epilepsy. Our results have been, indeed, almost valueless, for, with all our dosing with bromides, borax, belladonna, and so on through the alphabetical index of the Pharmacopœia, it is extremely doubtful if in ordinary practice one per cent. of the cases of idiopathic epilepsy are cured. Besides the practical incurability and hopelessness of the disease, its victims have suffered untold sorrows in the way of negligence and ill-treatment at the hands of the communities in which they live.

It is a peculiarity of this disease that the seizures may be momentary, or may last for a few minutes only, recurring sometimes frequently, sometimes daily, and sometimes months apart, thus robbing the sufferers of their consciousness and faculties, for brief periods of time at long or short intervals. Between the attacks they may be as rational and as well qualified for all the vocations, duties, and social privileges of life as any other human being.

These facts do not concern only a few members of a community. Epilepsy is a widespread disorder, and it has been calculated that one person in five hundred is thus afflicted. Thus there would be in the neighborhood of one hundred and thirty thousand such unfortunates in the United States alone, and over twelve thousand in the State of New York. Even supposing this percentage to be exaggerated to a very great extent, and that the actual ratio were one to one thousand, the number of epileptics would still be enormous, and would constitute a very large part of our defective classes.

Outside of the efforts, thus far comparatively futile, of physicians to alleviate their purely physical infirmities, and to reduce the number and severity of the attacks, nothing has been done until late years to provide for their mental development and to meet the peculiar conditions of life which they are called upon to endure. Thus no general hospital will receive such cases for treatment, because of the incurable and unpleasant nature of their malady; while much of the time thoroughly capable of acquiring an education, they are debarred for obvious reasons from the schools; the churches are closed to them; very few care to employ epileptics in shops, stores, or offices, or are willing to teach them trades; few epileptics are at liberty to enjoy the companionship of their fellows, who rather are inclined to shun their unfortunate brethren. Thus every avenue for mental or moral development, for occupation, for association with the rest of mankind is closed to them. They are even burdensome to their families. It is little wonder, then, that many of them grow up dull and ignorant, intellectually feeble, normally depraved, irritable in temper, with tendencies to retrogression and degeneration rather than to advance. A few of them become insane and are sent to insane asylums. Others, not insane, but ill adapted for existence under such miserable conditions, drift to the only homes offered them, the almshouses. The almshouse and the asylum are their only refuge when abandoned by their friends. In the State of New York, for instance, where there are twelve thousand epileptics, some four hundred or more are in insane asylums, and some six hundred in the county poorhouses. The rest of these are scattered throughout the State, in their own families, among the rich and the poor, in ratio to population and to the relative proportions of these classes. Many are so slightly affected that they are able in spite of their seizures to pursue some of the ordinary vocations of life. Thus I know personally of a doctor, clergyman, several bookkeepers, a bank president, a stock-broker, several clerks, some dressmakers, shoemakers, masons, and a telegraph operator who are epileptics, and yet able to carry on useful pursuits, albeit under adverse conditions. To all of us are familiar certain well-known historical or literary characters in whom epilepsy failed to restrict the development of their genius, such as Cæsar, Napoleon, Molière, Petrarch, Dostojewsky, and others.

It would seem, therefore, from the above facts that, although there is such a thing as epileptic insanity, the

proportion of insane epileptics to sane epileptics is really very small, much less than ten per cent. taken at the utmost, and that this ratio may be reduced by affording these unfortunates such opportunities for mental and moral development as are enjoyed by other and more happily situated citizens; and not only may the percentage of insanity be reduced, but the comfort and prosperity of all epileptics be increased by proper provision on the part of the State, or through private channels, of institutions of a peculiar character adapted to their peculiar wants. A large public hospital is very far from meeting their requirements, for, as has already been shown, medicinal treatment is uncertain and unpromising. Insane asylums should receive but very few, and almshouses none at all. What is demanded is an institution on the community or village plan, where medical treatment (such as it is) may be given to every member, and where every sort of education, employment, and social privilege commensurate with his needs and conditions may be extended to every beneficiary.

The colony system only can attain this object. A colony for epileptics is not an impracticable scheme proposed by visionaries. It is already an accomplished fact. The Bethel Epileptic Colony, at Bielefeld, in the province of Westphalia, near Hanover, Germany, was founded by Pastor von Bodelschwingh, over twenty-five years ago. He purchased a small farm with one house, and with four epileptics as a beginning, established a charity which for nobility of conception and success in its results has nowhere an equal. It seemed to its beneficent founder feasible to create a refuge where these sufferers might be cured, if curable, might have a home if recovery were impossible, might learn trades, and the great majority become educated, useful, and industrious citizens. From that small beginning there has been a gradual evolution of his idea, until now there are over one thousand epileptics, resident in some sixty or more houses scattered irregularly but picturesquely over a large farm. Everyone who visits this unique colony is deeply impressed with the happiness, contentment, and prosperity everywhere apparent among the inhabitants of this little epileptic world. He sees that it is no longer an experiment, and the previously unanswerable objections to such aggregations are, by its success, answered and silenced. At the time of my visit to Bielefeld, in 1886, there were but eight hundred and twenty-five epileptic patients. The employments were numerous and varied. A school provided instruction for some one hundred and fifty pupils of both sexes. All branches were taught. The dairy and the farm and garden occupied the attention of the greatest number of patients, especially as a large trade in vegetable and flower-seeds was carried on by the colony.

Among the shops for epileptic workmen were those for carpenters, cabinet-makers, painters and varnishers, printers, bookbinders, blacksmiths and foundrymen, tailors, and shoemakers; and among the stores were a grocery, pharmacy, book-store, and a seed-store. The carpenters aided in the building and furnishing of new houses. Plans and drawings for new buildings were made in the architects' room. Epileptics were employed in all the departments of industry relating to building. Books were printed and bound, and sold here, especially popular works for moral and religious instruction. The illumination of mottoes for hospital wards and schoolrooms, and the coloring of picture-cards were features of the work performed; washing, cooking, knitting, sewing, and fancy-work employed many. A bureau had been established for the collection and sale of museum objects, such as antiquities, articles of ethnographic and historic interest, autographs of distinguished people, coins, stamps, bronzes, gems, engravings, etc., and specimens from the animal, vegetable, and mineral kingdoms. For men alone there were over thirty different callings.

The houses presented great diversity of architecture and position. They were well separated, generally inclosed in individual gardens, surrounded by fences or hedges and many trees, and altogether exhibited the home-likeness of a country village, with little or nothing to suggest the restraints and discomforts of large institutions. There was one small cottage set aside for such cases as should become mildly insane, but bad cases of actual insanity were sent to insane asylums. Everything had been thought out carefully for the perfect evolution of this little social world, not only the multiplicity and details of occupations which would give each member of the community his choice of callings, but even the avocations, games, amusements, entertainments that might tend to divert his mind from the contemplation of his misfortunes. And since my visit the colony has continued to expand, to develop new and valuable features, and to confer its blessings upon large numbers of persons afflicted with this disease.

Taking Bielefeld as a model, nine other similar epileptic colonies have been established in Germany, one at Zürich, in Switzerland, and one in Holland. Most of these are not conducted by the state, but are under the jurisdiction of private or church charities. None of them are altogether self-supporting, but some of them approach very near it.

It should be stated that before the founding of the Bethel colony at Bielefeld, a somewhat similar institution, though on a much smaller scale, was begun in France, at a village called La Force, near Lyons. Over forty years ago a noble clergyman named John Bost established this institution, and it is in a flourishing state, doing a vast amount of good and redounding to the credit of his creative genius.

It has been found in all of these colonies that no harm is done by bringing epileptics into contact with each other. They feel on an equality with their fellows in such a place, losing that sense of isolation and singularity which they cannot but observe, in the ordinary world as separating them from the rest of mankind. They enjoy caring for each other and being kind and helpful to their fellow-sufferers. It has been noted, too, that the number of seizures almost always diminishes upon entering upon the new and more hopeful and encouraging life begotten in the busy community.

Within two or three years interest has been awakened in other countries in the matter of provision for epileptics, notably so in America and England, where their peculiarly sad condition had never been noted nor considered. In 1890 Ohio took steps toward the establishment of an institution for epileptics, a commission, consisting of Messrs. J. L. Vance, C. C. Waite, and one other having been appointed by Governor Campbell, pursuant to an act of the Legislature, to select a site and prepare plans for the purpose. Of various sites examined, one at Gallipolis seemed best adapted for the project, and here a tract of one hundred acres was presented to the State by the citizens for the institution. To the writer, who was consulted upon the subject of site and plans, this seemed to be the best location offered, for, although an insufficient space for a large institution, there was plenty of land adjacent which could be subsequently added to the original tract. Contrary to the advice of the writer, the architect felt obliged, probably owing to the demand of the community of Gallipolis for an institution of striking proportions, to group the buildings on a symmetrical plan, such as is frequently carried out in public establishments for the insane. The Ohio epileptic hospital is built on the pavilion or cottage plan, a large number of these being grouped about the centre or administration building. It will therefore not meet in this important particular the requirements of a colony for epileptics, although in respect to provisions for school-buildings, shops, and the like, an effort has been made to fit the institution for the particular kind of care needed by this class. The name of the institution for epileptics in Ohio is also unfortunately chosen, for it is called "The Asylum for Epileptics and Epileptic Insane." The corner-stone was laid with appropriate ceremonies November 12, 1891, an interesting address and historical review being given by General Roeliff Brinkerhoff, President of the Ohio State Board of Charities. Three of the buildings were completed and made ready for occupancy in 1892, and nine additional cottages are

now in course of construction, the last Legislature having made a liberal grant for the purpose.

In California detached buildings are being erected upon the grounds of the California Home for Feebleminded in Sonoma County, with the view of accommodating the epileptics dependent upon the State in pleasant quarters.

Active measures are being carried out also in Massachusetts, Pennsylvania, Wisconsin, and Illinois, for the purpose of procuring State care and separate provision for the same class of unfortunates.

Next to Ohio, the State of New York has manifested the most interest in her epileptic dependents, and in the winter session of 1891–92 a law was passed by the Legislature making the State Board of Charities a Commission to select a site and prepare plans for an institution for epileptics. The law was authoritative in requiring the tract of land secured for the purpose to be four hundred acres or more in extent, and the whole scheme of buildings to be arranged on the colony or village plan. A committee of the State Board of Charities, consisting of Messrs. Oscar Craig, William P. Letchworth, and Peter Walrath, has been busy all of the past summer and autumn (1892) in examining a large number of localities which they were invited to inspect by the officers of various counties. In their report made to the Legislature on Wednesday, January 11, 1893, the State Board of Charities unanimously recommended for the proposed colony a site in Livingston County, consisting of over eighteen hundred acres, the property of the "Shakers," now known as the Sonyea Society of United Christian Believers. The Shakers have dwindled in numbers to such an extent that they decided to give up this colony and rejoin the mother colony near Watervliet, N. Y. The land is beautifully situated in the Genesee Valley, near the town of Mount Morris, and in one of the finest regions of the State. It is exactly fitted to meet the wants of a model colony for epileptics. It is traversed by two streams. One of these, the Cashauqua Creek, flows through the middle of the land in a deep gorge, with a fall of one hundred feet. This gorge and creek are of immense advantage for the complete separation of the sexes in free colony life. The supply of water is abundant, and the conditions for good sewerage perfect and adequate in every respect. The Western New York & Pennsylvania Railroad runs through the land, and two great trunk lines, the Erie Railway and the Delaware & Lackawanna Railroad, are within a mile of the proposed colony. The soil is exceedingly fertile and well adapted for all manner of agriculture, horticulture, the production of berries and fruits for canning industries, and the raising of garden produce and seeds of all kinds. It has some stone and brick-clay, which will prove useful in the development of certain forms of out-of-door employments. It already contains scattered buildings for the accommodation of three hundred patients.

The law which has been introduced into the present session of the New York Legislature embodies provisions for the purchase of this tract of land, and also for the methods of management, government, and admission of patients to the colony. As some of these may be useful to those interested in the establishment of similar institutions, a few of the chief points will be mentioned here and the entire law given below.

The name of the institution is "The Sonyea Colony." Thus any direct reference to its object is avoided in the title. The word "Sonyea" is an old Indian word, meaning sunshine, and is historical in that this point was once the site of an ancient Indian village of the same name. For the present all insane epileptics are to be excluded, but probably ultimately there will be some building for the insane, especially for such as become mentally deranged temporarily while residents of the colony, since their removal from the happy influences of the community system to an asylum for the insane would be very depressing and tend to retard rather than promote their recovery.

There are to be nine managers appointed by the Governor, two of whom are to be women and two to be physicians. They are to represent the eight judicial districts of the State of New York, an additional member to represent the City of New York.

The colony is to have a medical superintendent, steward, matron, and such teachers and other assistants as are necessary.

The main object of the colony is to provide for the indigent epileptics of the State, but private patients will also be admitted to an extent to be determined by the Board of Managers. Epileptics of all ages are to be received and cared for; minors are detained by authority delegated by the parents or guardians; adults are free to go or remain, as they choose, there being no deprivation of liberty of any kind by methods of legal commitment, such as are necessary in asylums for the insane. The charge for maintenance of indigent patients is to be borne by the State, and a limit of $250 per annum per capita is established by the law. But it is expected that the colony will eventually become, to a very great extent, self-supporting.

Patients that become insane are to be sent to asylums in the districts from which they come, in accordance with the lunacy statutes.

A special pathologist to reside in the community and devote his sole attention to the discovery of the causes and cure of epilepsy is one of the features ultimately contemplated in connection with this great institution.

An Act to Establish an Epileptic Colony.—Section 1. Sonyea Colony. There shall be established in Livingston County, in this State, a colony for epileptics, to be known as the Sonyea Colony.

Sec. 2. Objects of such Colony. The objects of such colony shall be to secure the humane, curative, scientific, and economical treatment and care of epileptics, exclusive of insane epileptics; to fulfil which design there shall be provided, among other things, a tract of fertile and productive land, in a healthful situation, with an abundant supply of wholesome water, sufficient means for drainage and disposal of sewage, and sanitary conditions; and there shall be furnished, among other necessary structures, cottages for dormitory and domiciliary uses, buildings for an infirmary, a school-house, and a chapel, workshops for the proper teaching and productive prosecution of trades and industries; all of which structures shall be substantial and attractive, but plain and moderate in cost, and arranged on the colony or village plan.

Sec. 3. Managers of the Colony. There shall be a board of nine managers of the Sonyea Colony, seven of whom shall be men, and two of whom shall be women, appointed by the Governor, by and with the advice and consent of the Senate. Two of said managers shall be well-educated physicians; and all of them shall be citizens of the State, and residents respectively as follows: one in each of the eight judicial districts of the State, with one additional manager for the city and county of New York; but no manager shall reside in the town where said colony is located, or in Livingston County. The full term of office of each appointed manager shall be eight years, after the first appointments; and the term of office of one of such managers shall expire annually. To effect such order of expiration of terms of managers, the first appointments shall be made for the respective terms of eight, seven, six, five, four, three, two, and one years. Appointments of successors, and of persons to fill vacancies occurring by death, resignation, or failure in attendance at meetings shall be made without unnecessary delay. Failure of any manager to attend in each year the whole of two stated meetings of the board, shall cause a vacancy in his office.

The managers shall receive no compensation for their services, but shall be allowed their reasonable travelling and official expenses, when duly verified and approved by an auditing committee of the board, and duly presented to the Treasurer of the colony for payment.

Sec. 4. Land. The Board of Managers, within sixty days from their appointment, shall submit to the Attorney-General the land contract with option in the State, reported to the Legislature by the State Board of Charities at this session, and an official search and abstract of the

title of the tract of land described in said contract, containing eighteen hundred acres, more or less, lately occupied and owned by the United Society of Christian Believers, situated in Livingston County; and if such title be approved by the Attorney-General, and certified by him to be good and free from incumbrance, the Board of Managers shall, within thirty days thereafter, accept a good and sufficient deed of conveyance of said tract of land to the State, to be approved by the Attorney-General; and thereupon the Treasurer of the State, on the warrant of the Comptroller, shall pay therefor, as hereinafter provided, the consideration of $125,000, with proportionate reduction for deficiency, if any, in the quantity of land, which is assumed in said contract to be at least eighteen hundred acres for said purchase price.

Provided, that if such title shall not be approved, or such deed with a good title free from incumbrance cannot be secured, the Board of Managers shall, so soon as practicable, report the facts to the Legislature.

Sec. 5. Buildings and Improvements. Upon securing the conveyance of said tract of land to the State, with the approval of the Attorney-General as aforesaid, the Board of Managers shall immediately put the premises thus conveyed into proper condition for reception of patients; and shall receive them gradually and as rapidly as practicable; and for such uses and purposes shall utilize the present buildings and improvements upon said premises, and adopt a general design including the same, and the recommendations of the State Board of Charities in its said report, and subsequently from the beginning to the end, make all buildings and improvements subserve such design and recommendations and true economy.

Sec. 6. Donations in Trust. The managers may take, and hold in trust for the State, any grant or devise of land, or any gift or bequest of money or other personal property, or any donation, to be applied, principal or income or both, to the maintenance and education of epileptics, and the general uses of the colony.

Sec. 7. State Board of Charities. The Board of Managers of the Sonyea Colony shall annually, on or before the first day of November, for the preceding fiscal year ending September 30th, report to the State Board of Charities the affairs and conditions of the colony, with full and detailed estimates of the next appropriation required for maintenance and ordinary uses and repairs; and of special appropriations, if any, needed for extraordinary repairs, renewals, extensions, improvements, betterments, or other necessary objects; as also for the erection of additional buildings needed by reason of over-crowding, and in order to prevent the same, or to meet the need of sufficient accommodations for patients seeking admission to the colony, and the State Board of Charities shall, in its annual report to the Legislature, certify what appropriations are, in its opinion, necessary or proper.

The said colony shall be subject to the visitation and supervision and to the general powers of the State Board of Charities.

Sec. 8. Powers and Duties of Managers. Five members of the Board of Managers shall constitute a quorum for the transaction of business. The Board shall have the government of the patients, officers, employees, inmates, and inhabitants of the colony, and the general direction and control of all the persons, property, and concerns of the colony, not otherwise provided for by law; including the purchase of supplies and of raw materials for the trades and industries of the colony, and the sale and disposal of the manufactured products and the produce of the land, through its officers or agents, and the supply of necessary assistance to educate and profitably employ the labor of the patients; and shall take charge of the general interests of the colony, and see that its general design is carried into effect, and everything done faithfully and according to the requirements of the Legislature and the by-laws, rules, and regulations of the colony.

The managers shall elect from their number a president and a secretary, and may secure a seal. Documents and papers may be attested by the secretary, with, or without a seal; and when attested under seal shall be received in evidence as if duly acknowledged before an officer authorized to take acknowledgments of deeds.

The managers shall establish such by-laws as they may deem necessary or expedient for regulating the appointments, powers, and duties of officers, teachers, attendants, and assistants, for fixing the conditions of admission, treatment, education, support, and discharge of patients, and for conducting in a proper manner the business of the colony; and they shall ordain and enforce a suitable system of rules and regulations, for the internal government, discipline, and management of the colony.

The managers shall maintain an effective inspection of the affairs and management of the colony, for which purpose they shall meet at the institution at least twice in each year, at such times as the by-laws shall prescribe, provided that their annual meeting shall be held on the fifteenth day of October.

A committee of three managers, to be appointed by the Board at the annual meeting thereof, shall visit the colony once in every month, and perform such other duties and exercise such other powers as shall be prescribed in the by-laws or directed by the Board.

The Board shall keep in a bound book to be provided for the purpose a fair and full record of all its doings, which shall be open at all times to the inspection of its members, the members and officers of the State Board of Charities, and all persons whom the Governor or either house of the Legislature may appoint to examine the same.

Sec. 9. Officers of the Colony. The Board of Managers shall appoint, outside its members, two officers, namely: a superintendent of the colony, who shall be a well-educated physician and a graduate of a legally chartered medical college, with an experience of at least five years in the practice of his profession; and a treasurer, who shall reside in the county of Livingston, and shall give an undertaking to the people of the State, for the faithful performance of his trust, in such penal sum and form and with such sureties as the Comptroller shall approve.

Said officers and each of them may be discharged or suspended at any time by the said Board in its discretion.

The superintendent shall appoint a steward and a matron, who, with the superintendent, shall constantly reside in the colony, and he shall employ an experienced and competent bookkeeper, and such teachers, attendants, and assistants as he may think necessary or proper economically and efficiently to carry into effect the design of the colony; and he shall prescribe their several duties and places and fix their compensation; and he may, at any time in his discretion, suspend or discharge any of them.

The Board shall determine the annual salaries and allowances of the superintendent, steward, and matron, not exceeding, in addition to maintenance supplies, the following sums for salaries: Four thousand dollars to the superintendent; fifteen hundred dollars to the steward; fifteen hundred dollars to the matron, and the Board shall determine the annual salary of the treasurer of the colony, not exceeding two thousand dollars.

Such salaries and allowances shall be paid quarterly on the first days of October, January, April, and July, each year, by the treasurer of the colony, on presentation of the bills therefor, audited, allowed, and certified as prescribed in the by-laws.

Sec. 10. Duties of Superintendent. The superintendent shall be the chief executive officer of the colony, and, subject to the supervision and control of the Board of Managers, he shall discharge the following among other duties:

1. Oversee and secure the individual treatment and personal care of each and every patient of the colony while resident therein, and the proper oversight of all the inhabitants thereof.

2. Have the general superintendence of the buildings, grounds, and farm, with their furniture, fixtures, and

stock, and the direction and control of all persons employed in and about the same.

3. Give, from time to time, such orders and instructions as he may deem best calculated to induce good conduct, fidelity, and economy in any department of labor, or of education or treatment of patients.

4. Maintain salutary discipline among all employees, patients, and inhabitants of the colony, and enforce strict compliance with his instructions and uniform obedience to all the rules and regulations of the colony.

5. Cause full and fair accounts and records of the entire business and operations of the colony, with the condition and prospects of the patients, to be kept regularly, from day to day, in books provided for that purpose.

6. See that such accounts and records shall be fully made up to the first days of April and October in each year, and that the principal facts and results, with his report thereon, be presented to the Board at its semi-annual meetings.

7. Conduct the official correspondence of the colony and keep a record or copy of all letters by himself and by his clerks and agents, and files of all letters received by him or them.

8. Prepare and present to the board at its semi-annual meetings a true and perfect inventory of all the personal property and effects belonging to the colony, and account, when required by the Board, for the careful keeping and economical use of all furniture, stores, and other articles furnished for the colony.

9. Keep a record of all applications for admission of patients, and enter in a book, to be provided and kept for that purpose, at the time of the admission of each patient to the colony, a minute, with the date, name, residence of the patient, and of the persons on whose application he is received, with a copy of the application, statement, certificate, and all other papers received relating to such epileptic patient, the originals of which he shall file and carefully preserve, and certified copies whereof he shall forthwith transmit to the State Board of Charities.

Sec. 11. Duties of Treasurer. The treasurer, among his other duties, shall perform the following:

1. Have the custody of all moneys, notes, mortgages, and other securities and obligations belonging to the colony.

2. Keep a full and accurate account of all receipts and payments in such form as directed in the by-laws, and such other accounts as shall be required of him by the managers.

3. Balance all the accounts on his books on the first day of each October and make a statement thereof, and an abstract of all the receipts and payments of the past year; and, within three days thereafter, deliver the same to the auditing committee of the managers, who shall compare the same with his books and vouchers and verify the same by a further comparison with the books of the superintendent, and certify the correctness thereof to the managers at their annual meeting.

4. Render a quarterly statement of his receipts and payments to such auditing committee, who shall, in like manner as above, compare, verify, report, and certify the result thereof to the managers at their annual meeting, who shall cause the same to be recorded in one of the books of the colony.

5. Render a further account of the state of his books and of the funds and other property in his custody whenever required by the managers.

6. Receive for the use of the colony any and all sums of money which may be due upon any obligations or securities in his hands belonging to the colony, and any and all sums charged and due to the asylum for the support of any patient therein, or for actual disbursements made in his behalf for necessary clothing and travelling expenses, and any and all sums of money due to the colony.

7. Prosecute an action in the name of the people of the State to recover any sum of money that may be due or owing to the colony from all sources, including the bringing of suit for breach of contract between private patients or their guardians and the managers of the colony.

8. Execute a release and satisfaction of a mortgage, judgment, or other lien in favor of the colony when paid, so that the same may be discharged from record.

9. Pay the salaries of the superintendent, treasurer, the matron, and the steward of the colony, and of employees duly appointed as aforesaid, and the disbursements of the officers and members of the board as aforesaid.

The treasurer shall have power to employ counsel, subject to the approval of the Board of Managers.

Sec. 12. Designation and Admission of Patients. There shall be received and gratuitously supported in the colony, epileptics residing in each judicial district, who, if of age, are unable, or, if under age, whose parents or guardians are unable to provide for their support therein, and who shall be designated as State patients. Such additional number of epileptics, whether of age or under age, as can be conveniently accommodated, shall be received into the colony by the managers on such terms as shall be just, and shall be designated as private patients.

Epileptic children shall be received into the colony only upon the written request of the persons desiring to send them, stating the age, place of nativity, if known, Christian and surname, the town, city, or county in which such children respectively reside, and the ability of their respective parents or guardians or others to provide for their support, in whole or in part, and if in part only, stating what part; and stating also the degree of relationship or other circumstances of connection between the patients and the persons requesting their admission, which statements, in all cases of State patients, must be verified by the affidavits of the petitioners and of two disinterested persons, and accompanied by the opinion of a qualified physician, all residents of the same county with the epileptic patient, and acquainted with the facts and circumstances stated, and who must be certified to be credible by the County Judge or Surrogate of the county, and such Judge or Surrogate must also certify, in each case, that such State patient is an eligible and proper candidate for admission to the colony.

State patients, whether of age or under age, may also be received into the colony upon the official application of a County Superintendent of the Poor, or of the Commissioners of Charity or Overseers of the Poor of cities or towns having such officers.

It shall be the duty of the Superintendent of the Poor in every county, and of the Overseer, Commissioner, or Board of Commissioners of every city having supervision of the poor, to furnish annually to the State Board of Charities a list of all epileptics in their respective jurisdictions, so far as the same can be ascertained, with such particulars as to the condition of each epileptic as shall be prescribed by the said State Board.

Whenever an epileptic shall become a charge for his or her maintenance on any of the towns, cities, or counties of this State, it shall be the duty of all Overseers or Charity Commissioners, or other officers of the poor of such city, and of the County Superintendent of the Poor, and of the Supervisors of such county, to place such epileptic in the said colony.

Any parent, guardian, or friend of an epileptic child within this State may make application to the Overseer or Charity Commissioner, or Board of Commissioners or other officers having charge of the poor of any city or town, or the Superintendent of the Poor of any county, or the Board of Supervisors or any Supervisor of such county where such child may be, showing by satisfactory affidavit, or other proof that the health, morals, comfort, or welfare of such child may be endangered or not properly cared for if not placed in such colony; and thereupon it shall be the duty of such Overseer, Charity Commissioner, Poor Officer, Superintendent of the Poor, or Supervisor or Board of Supervisors, to whom such application may be made, to place such child in the said colony, provided that in all cases not properly coming under section thirteen relating to the support of State

patients, the Board of Supervisors shall provide for the support of such cases, and may recover the same from the parents or guardians of such children.

In the admission of patients, preference shall always be given to poor or indigent epileptics or the epileptic children of poor or indigent persons, over all others; and preference shall always be given to such as are able to support themselves only in part, or who have parents able to support them only in part, over those who are able, or who have parents who are able wholly to furnish such support.

Sec. 13. Support of State Patients. Each indigent patient and each patient who is the child of indigent parents received into the colony as aforesaid, shall be provided with proper board, lodging, medical treatment, care, and tuition; and shall be denominated State patient; and the managers of the colony shall receive for each of such patients so provided for, the sum necessary for such provision and purpose, not to exceed the sum of two hundred and fifty dollars per annum, the intent of this act being that the colony shall be self-supporting so far as practicable; which payments, if any, shall be made by the Treasurer of the State, on the warrant of the Comptroller, to the treasurer of the said colony, on his presenting the bill of the actual time and number of patients in the colony, signed and verified by the superintendent and treasurer of the colony, and by the president and secretary of its Board of Managers.

The Supervisors of any county, from which such State patients may have been received into the colony, shall cause to be raised annually, while such patients remain in the institution, the sum of thirty dollars, for the purpose of furnishing suitable clothing for each of such State patients; and the same shall be paid to the treasurer of the colony, on or before the first day of April of each year.

Sec. 14. The Support of Private Patients. The superintendent of the colony may agree with any epileptic who may be of age, or his committee or guardian, or with the parents, guardian, or committee of any epileptic child, or with any person, for the entire or partial support, maintenance, clothing, tuition, training, care, and treatment of such epileptic in the colony, on such terms and conditions as may be prescribed in the By-laws, or approved by the managers. Every parent, guardian, committee, or other person applying for the admission into the colony of an epileptic who is, or whose parents or guardians are, of sufficient ability to provide for his support and maintenance therein, shall, at the time of his admission, deliver to the superintendent an obligation, with one or more sureties, to be approved by the superintendent and treasurer, in such manner and penalty as the managers shall prescribe, to the effect that the obligors will pay to the treasurer of the colony all sums of money at such time or times as shall be so agreed upon, and remove such epileptic from the colony, free of expense to the managers, within twenty days after the service of the notice hereinafter provided for. If such epileptic, his parents or guardian are of sufficient ability to pay only a part of the expenses of supporting and maintaining him at the institution, such undertaking shall be only for such partial support and maintenance and for removal from the institution as above mentioned; and the superintendent may take security by such obligation, or in his discretion by note or other written agreement, with or without sureties as he may deem proper, for such part of such expenses as the epileptic, his parents or guardians are able to pay; but such exercise of discretion shall be subject to the approval of the treasurer and a committee of the managers, in the manner that shall be prescribed in the By-laws. Notice to remove a patient shall be in writing, signed by the superintendent and directed to the epileptic, his parents, guardians, committee or other person upon whose request the patient was received at the colony, at the place of residence mentioned in such request, and deposited in the post-office at Sonyea, or any post-office in Livingston County, with the postage prepaid.

Sec. 15. Discharge of Patients. The superintendent of the colony, with the approval of the managers or of its committee duly empowered, shall have power to discharge patients; provided that no epileptic patient shall be returned to any poorhouse directly through a superintendent of the poor, or otherwise.

In case a patient, not an epileptic, shall be sent to the colony, through mistaken diagnosis of his disease, or other cause, and there received, such patient shall be returned to, and the travelling expenses of such return shall be paid by the person who sent him or her to the colony.

Should an epileptic patient become insane, and be so certified, as prescribed by the statute, such patient, if a State patient, shall be sent to the State Hospital of the district of which he was a resident just prior to his admission to the colony, or, if a resident of New York to the asylum of that county, of if a resident of Kings to the asylum of that county. Said State patient shall be sent to said State Hospital, or County Asylum, in a manner prescribed by the President of the State Commission in Lunacy, at the expense of the State, and any State Hospital or County Asylum to which said patient is to be sent may be required, by and under the regulations made by said President, to send a trained attendant to bring the patient to the hospital or asylum.

In all cases there shall be provided a female attendant for every female patient.

The bills for the reasonable expenses incurred in the transportation of State patients to the State Hospitals, or Asylums of New York and Kings Counties, after they have been approved in writing by the State Commission in Lunacy, shall be paid by the Treasurer of the State on the warrant of the Comptroller from the funds provided for the support of the State Hospitals.

In case any insane person, his relatives, guardians, or friends desire that he may become an inmate of any State Hospital situated beyond the limits of the district of which he was formerly a resident, or outside of New York and Kings, if a resident of either of those counties, and there be sufficient accommodation there to receive him, he shall be received there upon the same grounds and terms, and the same in all respects as are or may be at any time provided by law, respecting transfers of other insane persons.

Private patients, who may become insane, and are so certified, as prescribed by law, shall be committed, subject to the regulations of the State Commission in Lunacy to such institution for the insane as may be designated by such patient, his or her relatives, guardians, or friends, all travelling and other expenses of removal to be paid by them.

After any patient has been delivered to the managers or officers of any of said hospitals or asylums, the care and custody of the managers of the colony over such insane person shall cease; and after any patient shall, as aforesaid, be so certified to be insane as prescribed by law, such patient shall come under the supervision of the State Commission in Lunacy.

Sec. 16. Apportionment of State Patients. Whenever applications are made at one time for admission of more State patients than can be properly accommodated in the colony, the managers shall so apportion the number received that each county may be represented in a ratio of its dependent epileptic population to the dependent epileptic population of the State as shown by statistics furnished by the State Board of Charities.

Sec. 17. Notice of Opening of Colony. So soon as the colony shall be ready for the reception of patients, it shall be the duty of the Board of Managers officially to notify the County Clerks and the Clerks of the Boards of Supervisors of the respective counties of the State, and the Secretary of the State Board of Charities; and to furnish said clerks of the counties and of the Boards of Supervisors with the suitable blanks for admission and entrustments of epileptics to such colony.

Sec. 18. Appropriations. The sum of one hundred and fifty thousand dollars, or so much thereof as may be necessary, is hereby appropriated for the purposes of this act, out of any moneys in the treasury not otherwise appropriated. The Treasurer of the State shall, on the

warrant of the Comptroller, pay to the treasurer of the Board of Managers of said colony, such sums as may from time to time be required for the purchase of land, improvements, and betterments, erection of buildings and furnishing the same, heating, lighting, and ventilating the same, and putting the lands and buildings into proper condition for the reception of patients, not to exceed one hundred and twenty-five thousand dollars for the purchase of the land as hereinbefore provided, and not to exceed twenty-five thousand dollars for such other purposes; provided that such purposes and all requirements upon which such payments shall be made shall be certified to the Comptroller by said Board of Managers, in writing, specifying the items, the purposes for which the said sums are required, and be verified by the affidavit of the superintendent and treasurer of the colony, and of the president and secretary and majority of the said Board of Managers.

Sec. 19. This act shall take effect immediately.

While these measures have been in progress in the United States, a similar movement has been inaugurated in England. The Countess Meath has established at Godalming a small home for epileptics, in which instruction and occupation are among the principal features aimed at. There has been organized in Great Britain also a National Society for the Employment of Epileptics which numbers among its members many medical men of eminence and many citizens of wealth and influence. This society proposes to acquire a tract of land in England for the purpose of colonizing epileptics, according to the system herein advocated.

The care of the epileptic population is then to be summarized as follows:

All are to be treated in accordance with the usual regulations as to diet, hydrotherapy, and medicinal agencies, with the hope that in this way between one and six per cent. of them may be cured, and the disorder in a larger percentage ameliorated.

Out-of-door employment in agriculture and kindred pursuits is to be provided in abundance. All manner of trades and occupations are to be carried on in an epileptic community, organized on the village plan. Facilities for education are to be afforded to almost every extent.

Amusement and entertainment and the enjoyment of social intercourse are to be privileges from which no epileptic will hereafter be debarred.

In this way the happiness of a large number of these miserable creatures will be materially increased, in spite of the distressing disease which they are called upon to suffer, usually for the whole of their lives; and though remedial agents applied to their malady may prove inefficient, their fate can never be as wretched or hopeless as it has been throughout the world heretofore.

Although it is not given to every epileptic to describe his own sufferings as Dostojewsky does in his novel "The Idiot," or to delight the world with music as did the epileptic Handel, or with comedy as did Molière, or with poetry as did Petrarch, or with military exploits as did Cæsar and Napoleon, or with religion as did Mahomet and St. Paul, still it is a consolation to those afflicted with this malady to know that epilepsy and genius may coexist, and that the possession of the disease does not necessarily lead to mental and moral degeneration. The patient may not reach the highest position among mankind, but under the new dispensation he will not be withheld from any attainment in education, nor prevented from exercising all of his capabilities for his own support and for his own welfare and happiness.

ETHYL CHLORIDE. This has recently been introduced as a local anæsthetic, and promises to prove of decided value. It is obtained by saturating an artificially cooled alcoholic solution of chloride of zinc with hydrochloric acid gas. It is also obtained as a by-product in the manufacture of chloral. Its chemical formula is $C_2H_5Cl_4$. At ordinary temperatures it is a gas, but is easily compressed into a colorless liquid with a pleasant ethereal odor. Below 50° F. it remains a fluid, but at that temperature it is volatilized and becomes a light and very inflammable gas.

Advantage has been taken of its rapid evaporation to utilize the intense cold produced, as a local anæsthetic, in dental and minor surgical practice, and for the relief of the pain of superficial neuralgia. It has been used with satisfaction for the extraction of teeth, opening of abscesses, removing ingrowing toe-nails, and similar painful operations, and has been found to give instantaneous relief in facial neuralgia, intercostal neuralgia, and sciatica.

The method of utilizing this property has been made simple and easy by M. Mounet, of Lyons, who suggested the storing of the compressed fluid in small capsules and tubes, by which means it may be preserved without alteration for a great length of time. When the drug is required for use the point of the capillary tube is broken off, and the opening directed downward on the part to be anæsthetized. The heat of the hand is sufficient to raise the temperature of the fluid above its boiling point, and a stream of the rapidly volatilizing fluid issues as a spray, and may be applied to any part. The stream may be made weaker or arrested by simply closing the opening with the finger, or made stronger by grasping a larger portion of the tube and raising the temperature of its contents. It is considered best to hold the tube from six to ten inches away from the surface, to avoid excessive and useless cold. Each tube contains about two and a half drachms, which is sufficient to annul the sensibility of the skin and the parts immediately beneath, over a surface and to a depth sufficient for small operations. For the removal of teeth the spray is to be directed on the mucous membrane of the gum. The membrane is first dried and then rubbed with glycerine or oil, and the spray applied until the part becomes white. The sound teeth, as well as the mucous membrane of the mouth, must be protected by a napkin, and the patient directed to breathe only through the nostrils. It is said that the teeth may be extracted without pain by directing the spray against the cheek, over the inferior maxillary nerve for the lower jaw, and at the exit of the trigeminal nerve, in front of the ear, for the upper jaw.

It is simple in application and requires no apparatus, which gives it a decided advantage over methyl chloride, CH_3Cl, which has also been used for the same purpose. The low boiling-point of this older anæsthetic (− 1.4° F.)

requires a careful management to control its action and avoid excessive freezing and destruction of tissue. Methyl chloride also at times affects the system, causing more or less disturbance of the brain and mental faculties. Ethyl chloride in no way produces any effect beyond its local action. Its one objectionable feature is its great inflammability, which must be guarded against by performing the operation at a distance from a flame.

Drs. H. C. Wood and Cerna report in the *Therapeutic Gazette*, August, 1892, a series of experiments upon the anæsthetic properties of ethyl chloride when administered by inhalation. Anæsthesia was produced in the animal when the fluid was poured into a closed cone, almost impervious to air, and held closely to the nostrils. The anæsthesia was rapid and of short duration, ten grammes producing insensibility for only two minutes. It also caused the desired effect when injected into the veins, but failed to do so when the vapor was forced into the lungs through a tube inserted into the trachea.

As a result of their experiments they conclude: (1) That the chloride of ethyl is capable of acting as an anæsthetic, but that it is eliminated with extraordinary rapidity, and that its action is extremely fugacious; (2) that the anæsthesia which it produces is always accompanied by a fall of the blood-pressure, which is probably, at least in part, due to a direct depressing effect of the drug upon the heart; (3) that the action of the drug upon the circulation is in no way dependent upon its influence upon the respiration, although it is not certain that the pronounced depression of the blood-pressure is not a factor in influencing respiratory movement; (4) that, at least in the dog, chloride of ethyl produces at first an increase of the respiratory movement, either in rate or amount, or more commonly in each respect, but that finally respiration becomes slow, and at last stops abruptly; (5) that usually, if not always, the cessation of heart-beat and the arrest of respiratory movement occur as nearly simultaneously as may be. They think that the fugacious action and its depressing effects will prevent its becoming used as a safe anæsthetic, but are satisfied that the small amount that may be inhaled during its local use for dental purposes, has practically no effect on the system, as it is very rapidly eliminated.

Beaumont Small.

ETHYLENE BROMIDE. This organic compound has been introduced into therapeutics as a convenient means of supplying bromine in cases where its use is indicated for a prolonged period. The advantage claimed for it is, that it is not combined with potassium, sodium, or any basylous radicle, and its use does not disturb the digestion, the skin, or the mucous membranes, or produce any of the unpleasant effects that the older salts are liable to cause.

It is the di-brom derivative of ethane, in which each bromine atom is attached to a separate carbon atom; its chemical formula is $C_2H_4Br_2$. It is a colorless or faintly brown liquid, containing 90.9 per cent. of bromine. The odor is agreeable and taste sweetish. Its specific gravity is 2.163 at 69.8° F. Below 48° F. it becomes a solid, forming crystals. It is insoluble in water, soluble 1 in 4 of rectified spirit, and miscible in all proportions with absolute alcohol and oils.

The employment of ethylene bromide in epilepsy has been recommended by Dr. J. Donath.[1] He used it in a great number of cases, and reports the details of ten cases in which he was able to watch its effects carefully. As a substitute for the bromides he found it very satisfactory, and the results he considers were much better. The cases were all of long standing and had been subjected to many forms of treatment. Under its use the attacks became milder, shorter, and fewer in number, and in many instances assumed the character of *petit mal*. In three of the cases the convulsions were replaced by simple muscular twitchings without loss of consciousness.

The dose administered was six to twelve drops three times a day. It may be given in capsules with oil or in solution. The following preparations are recommended: (1) Ethylene bromide, 75 grains; oil of almonds, emulsion, 1,500 grains; oil of peppermint, 2 drops; dose, thirty drops three times a day, in a third of a glass of milk. (2) Ethylene bromide, 75 grains; rectified spirits, 75 grains; oil of peppermint, 2 drops; dose, five to ten drops three times a day. In preparing these mixtures the high specific gravity must not be forgotten, it being nearly two and a half times as heavy as water. Before using the drug Donath tested its action on himself, and found that in ordinary doses it did not produce any disturbing effects; but in large doses it was sometimes followed by nausea.

This drug must not be mistaken for ethyl bromide, which it resembles both in name and appearance. A case is reported[2] in which such a mistake was made with fatal consequences. A written order for the anæsthetic, ethyl bromide, was sent to a druggist, who supplied ethylene bromide. Ten drachms were inhaled without producing any insensibility or anæsthesia. The administration was followed by suppression of urine and uncontrollable vomiting, which continued until the patient died, upon the following day. At the post-mortem examination there was found an hyperæmia of the meninges of the brain, also of the lungs, spleen, and kidneys. The liver was much enlarged, of a dirty-yellow color, and the cells were affected by a granular degeneration.

Beaumont Small.

ÉTRETAT. One of the most frequented seaside resorts on the Channel coast. Étretat is in the Department of Seine-Inférieure, France. It is situated between two cliffs, over 250 feet high, and is famous for its picturesque appearance. It was formerly a mere fishing village, but is now very fashionable, so that at the height of the season, in July and August, it is often impossible to secure proper accommodation. Baughan, in the "Northern Watering Places of France," gives the following description of the bathing peculiarities:

The beach of Étretat is lower than the sea at the high tides, from which it is protected by a dyke of bowlders, which, however, is constantly being removed by the waves, which lash the shore with great violence at certain seasons of the year; so much so that it is the custom at Étretat every year at the *fête* of Ascension Day for the priests to go down to the shore to pronounce a benediction on the sea, and to exhort it to respect its limits. Picturesque and charming as Étretat is, the bathing is not so pleasant as in other places along the coast, for apart from the fact that the bowlders are not such a pleasant footing as sand, the bathing is dependent on the state of the tide, and, therefore, hours of meals, occupations, and even the amusements of the place, seem to depend on the tide.

Edmund C. Wendt.

EUGENOL, EUGENIC ACID, is formed from the oil of cloves by oxidation; it may also be obtained from other essential oils, as cinnamon, bay, pimento, sassafras. Its chemical composition is C_6H_3. $C_3H_5(OH)(OCH_3)$. It is an aromatic, oily liquid, colorless, with a strong clove odor. On exposure to the air it turns brown. It is readily soluble in alcohol but only very sparingly so in water. It forms compounds of a definite character with caustic alkalies. It possesses powerful antiseptic properties which are said to be superior to those of phenol. It has also been recommended as a febrifuge, but is inferior to salicylic acid, quinine, antipyrine, etc. Eugenol, which is somewhat analogous to guaiacol, has become of some importance on account of its being suggested for administration in tubercular diseases by Dr. Koch. He recommends its administration during the tuberculine treatment. The dose is forty-five minims during the day, dissolved in spirit and diluted with water. Applied locally, eugenol has a mild local anæsthetic action. It is useful for toothache and for painful affections of the skin; in the latter class of cases it is applied as an ointment with lanoline.

Two derivatives of eugenol—benzoyl-eugenol and cinnamyl-eugenol—have lately been introduced, and are be-

ing used in the treatment of tubercular affections. Their dose and action are as yet uncertain.

Benzoyl-Eugenol, the benzoate of eugenol, occurs in neutral acicular crystals, free from color and odor, but having a faint bitter taste, very slightly soluble in water, but freely in alcohol, chloroform, and ether. With concentrated sulphuric acid it gives a purple-red color, which is characteristic of eugenol; this reaction distinguishes it from benzosol, a compound of benzoyl and guaiacol (the latter gives a pale yellow color). Its melting-point is 158° F.

Cinnamyl-Eugenol also is formed in colorless, neutral crystals, free from odor and taste. Its solubility is the same as the benzoyl salt. With sulphuric acid it gives the same reaction as its fellow salt, but may be distinguished by its melting-point, 194° to 198° F.

Beaumont Small.

EUPHORBIA PILULIFERA. A plant of the order Euphorbiaceæ, which has been recommended as a remedy for spasmodic affections and neuroses of the respiratory tract. It is indigenous to Australia, Brazil, and other southern tropical countries. It derives its specific name from the seeds, which are held in capsules in the axils of the leaf, and when ripe are brown and hard. It is commonly known as the pill-bearing spurge. It is a very common annual herbaceous plant, and has a local reputation as a curative agent in all pulmonary troubles. Dr. Mattheson, of Queensland, was the first to call attention to its value in asthma, paroxysmal dyspnœa, whooping-cough, and other spasmodic affections. Later it was studied by Dr. Marsset, under the direction of Dujardin-Beaumetz, and the result of his researches was published in the *Therapeutic Gazette*, February, 1885. Its action is directed to the respiratory and cardiac centres, and causes a retardation of the respiration and pulse, and when death has been produced it arises from a paralysis of these organs. It does not influence any of the other organs of the body, but when administered it produces an irritant action on the gastric mucous membrane.

Its active principle is an acrid resin, which is soluble in water and dilute alcohol. Experiments on animals show that one part of the resin to one hundred of the animal, by weight, will produce a fatal result.

It has proved of service in all spasmodic affections of the bronchial tubes and lungs, in the dyspnœa of emphysema of the lungs, and in that due to cardiac affections. Dujardin-Beaumetz recommends it to be used in all cases in which iodide of potassium is used to relieve dyspnœa. It has also been used to relieve the spasms and distress of angina pectoris, and in hay asthma and coryza. In the latter diseases it rapidly checked the sneezing and other troublesome symptoms.

The dried plant is used and its virtues are said to be best extracted by water. A decoction may be made by steeping half an ounce of the plant in two quarts of water, the dose to be three or four wineglassfuls during the day. A tincture may be made of one part to five of proof spirit: dose, ten to fifteen minims, three times a day. It is advisable always to begin with small doses and gradually increase the amount, watching its effect, as its action is sometimes violent. The administration cannot be continued for a great length of time owing to its irritant action on the stomach.

Beaumont Small.

EUPHORIN (Phenyl-urethan. Carbonate of ethyl and phenyl). Its formula is $C_6H_5NHCOOC_2H_5$. This is a compound derived from aniline and is somewhat allied to acetanilide. It occurs as a white crystalline powder, with a faint aromatic odor and slight taste, almost insoluble in water, but freely soluble in weak alcohol and wines. It was introduced in 1890 by Dr. Sansoni to replace antipyrine, antifebrine, and other drugs of the same class. It was said to possess all their medicinal properties and to be devoid of their many objectionable effects.

In a large number of cases of fever due to various causes in which it had been used as an antipyretic the temperature fell quickly within one hour. The fall reached its maximum in about three hours, and lasted for five or seven hours. The subsequent rise of temperature was usually rapid. Its action was found to vary in different individuals. It is advised to commence with a dose of three grains, which may be increased until fifteen or thirty grains are given daily. In acute rheumatism fifteen grains daily caused disappearance of the swelling and pain in the joints and lowered the temperature. In chronic cases the results were not so satisfactory. Subsequent observers have also found it of benefit in sciatica, migraine, neuralgia, and in some cases of muscular rheumatism. As an external application its antiseptic properties have been made use of as an application to wounds, ulcers, burns, etc. Dusted on the surface it has acted very beneficially; the parts are rapidly rendered clean and healthy, the secretion is diminished, and cicatrization promoted. It does not cause pain or in any way prove irritating. It may also be used as an ointment. For internal administration it should be given in wafers, or in solution in weak alcohol or with wines. It must never be combined with antipyrine, as chemical decomposition takes place and a fluid results.

Beaumont Small.

EUROPHEN. This is one of the many compounds containing iodine and devoid of any disagreeable odor, that have been introduced as substitutes for iodoform. Chemically it is di-isobutylortho-cresol iodide, its formula being $\left(\begin{matrix}C_4H_9\\CH_3\end{matrix}>C_6H_3O\right)_2HI$. Its relation to cresol and iodine is much the same as that of aristol to thymol and iodine. It is prepared by adding isobutyl alcohol to ortho-cresol with zinc chloride, at a high temperature, which forms isobutyl ortho-cresol. This is dissolved in a dilute alkaline solution and then mixed with a solution of iodine in iodide of potassium, which yields a copious precipitate of the above compound. This is collected, washed, and dried in the dark.

It is an extremely light amorphous yellow powder, with an aromatic odor resembling saffron. It contains 27.6 per cent. of iodine. It is insoluble in water and glycerine, soluble in alcohol up to thirty per cent., and in ether, chloroform, collodion, and fatty oils up to twenty-five per cent. It must be excluded from light and heat, as it is readily decomposed. In contact with water it is slowly decomposed, yielding free iodine. Alcoholic and ethereal solutions also evolve iodine if kept for a long time.

Starch or starchy preparations should never be prescribed with europhen, as the reaction between the two is rapid, particularly when water is added to the mixture, or when the fluid secretions cause the powder to evolve the iodine freely. The metallic salts, especially zinc and mercury, so freely used in dermatology, should never be combined, on account of the well-known incompatibility of these metals. The most durable mixtures are those prepared with oil or lard, vaseline or lanoline. The latter is to be preferred, as it allows of a greater amount of absorption of the fluids, and consequently a more thorough action of the application. Europhen is, however, a dry antiseptic, and is most effective when applied as a powder directly to the part. Its action is due to the continuous liberation of free iodine, which commences as soon as the drug comes in contact with moisture. This gradual escape of iodine, together with the well-known antiseptic properties of the cresol also present, has a very decided effect in checking the growth of bacteria, and also prevents the reducing power of bacteria having an anaërobic growth. It, however, is devoid of bactericidal action, and in no way destroys bacteria or spores. Over iodoform it possesses certain advantages. It is free from the powerful penetrating odor that is so objectionable; its toxic properties are only evident after very large doses, and for internal use it may be administered without fearing any dangerous symptoms. As much as twenty-two grains have been taken daily, for three weeks, without the slightest discomfort. It is extremely light, being about

five times as bulky as iodoform, and readily adheres to the skin or mucous membrane.

The use of europhen is indicated in all cases where iodoform is employed in wounds and ulcers and ulcerated surfaces, and in diseased conditions of the nasal and pharyngeal cavities, of the vagina and uterus, and all mucous surfaces. In various forms of skin disease it has proved beneficial, especially the acute and chronic eczemas. It has also been found useful as an application in erysipelas. An alcoholic or ethereal solution, of the strength of ten per cent. of the powder, has been said to act remarkably well when applied to syphilitic ulcers and to the initial sores. It is also administered internally in all stages of syphilitic disease, but is most recommended as being very active in the third stage, and is thought to replace the iodide of potassium as a specific. The dose to commence with should be one-quarter of a grain, gradually increased to one or two grains. If it is administered too rapidly there is a danger of iodism manifesting itself. The same amount may be used hypodermically, a ten per cent. solution in oil being prepared for this purpose. For external use as an ointment the following has been selected as an excellent combination: Europhen, 3 parts; olive-oil, 7 parts; vaseline, 60 parts; lanoline, 30 parts. *Beaumont Small.*

EVIAN-LES-BAINS. A watering-place and climatic resort on the Lake of Geneva, France.

Location.—Evian is a little town, having a population of 2,600, situated on the southern or Savoy side of the Lake of Geneva. It is built close to the edge of the water, and lies directly opposite the city of Lausanne. It is pleasantly located, with charming views in all directions, and, apart from the popularity of its mineral springs, is known for the genial mildness and equability of its climate.

Access.—By rail or steamer from Geneva, also by rail from Aix-les-Bains.

Analysis.—There are six principal springs, all having about the same composition, and all very faintly mineralized. The temperature of the water is about 54° F. It is colorless, faintly alkaline, and so pure and agreeable to the taste that it is largely used as a mere table-water. The Source Bonnevie, according to an analysis of the *École des Mines*, contains in 1,000 grammes:

	Grammes.
Bicarbonate of lime	0.2210
Bicarbonate of magnesia	0.0150
Bicarbonate of soda	0.0200
Bicarbonate of potash	0.0070
Phosphate of soda	0.0017
Carbonic acid, free	0.0970
	0.3617

Traces of alkaline chlorides.

Indications.—A course of Evian waters is frequently prescribed to supplement the rigorous cure at Aix-les-Bains. According to Dr. Vintras ("Medical Guide to the Mineral Waters of France"), "the Evian waters are drunk, and used for baths and douches. As shown by the analysis, nothing in their chemical composition indicates their well-known therapeutical value. They agree perfectly with the stomach, and act as an excellent diuretic in cases of gravel, enlargements of the prostate, and catarrhal affections of the bladder and kidneys, by the species of irrigation which they produce in the interior of these organs. If there is irritability of the urinary passages, caused by the presence of a calculus, or after lithotritic operations, they are to be preferred to those of Vichy, Vittel, or Contrexéville, which in such cases would be much too exciting.

"Chronic affections of the digestive organs, such as dyspepsia, gastralgia accompanied by acid eructations, pyrosis, chronic irritation of the intestines, chronic diarrhœa, obstinate constipation, hemorrhoids, etc., are all treated with benefit at Evian. Patients suffering from the irritability which accompanies most forms of chronic neuralgia have been relieved from it, after using the waters for some days. It is supposed to have a calmative influence in all kinds of hypersensitive conditions."

The amount of water taken varies from two glasses to twenty-five per day. The baths are soothing and sedative, and patients generally sip several glasses of mineral water while in the tub.

Accommodation.—There are good hotels like the *Grand Hotel des Bains*, a Casino, and two thermal establishments with modern comforts and hydrotherapeutic appliances. Life is gay during the season, there being plenty of amusements. *Edmund C. Wendt.*

EXALGINE. This is the trade name of methylacetanilide. Its chemical formula is $C_6H_5NCH_3C_2H_3O$; it is formed by the addition of the methyl group, CH_3, to acetanilide, $C_6H_5NHC_2H_3O$, replacing one atom of hydrogen. It occurs as beautiful needle-shaped crystals, colorless, with a faintly aromatic odor and slightly pungent taste. It is almost insoluble in cold water, slightly soluble in hot, and very soluble in dilute alcohol. From sixteen to twenty grains may be dissolved in half a drachm of rectified spirit and this solution diluted with two or three ounces of water without producing any precipitation. Its melting-point is 212° F., and it may be heated to its boiling-point, 240° or 250° F., without causing decomposition. By the addition of soda it is decomposed and partially converted into methylaniline. Hydrochloric acid causes the same decomposition. The presence of methylaniline and other compounds of the same base may be detected by the irritating fumes produced when the impure salt is heated with alcoholic solution of potash and chloroform. Its purity may be further tested by dissolving in nitric acid, which forms a colorless solution; when heated this becomes of a bright yellow color, and evolves irritating fumes. Exalgine may be distinguished from acetanilide, phenacetine, and methacetine by treating two grains of the suspected salt with twenty minims of hydrochloric acid. Phenacetine remains undissolved; acetanilide dissolves but separates again in crystals; methacetine also dissolves and gradually colors the solution reddish-brown on the addition of one drop of nitric acid. Another test for the presence of phenacetine or acetanilide is to treat a chloroform solution with ten volumes of petroleum ether; if either of these substances is present a turbid mixture is formed.

Methylacetanilide was discovered in 1874 by A. W. von Hofman. Its therapeutic properties were studied to a certain extent by Kahn and Hepp during their researches upon acetanilide and other antipyretics, but it was not until March, 1889, that Dujardin-Beaumetz and Bardet made known its value as an analgesic, in a communication to the French Academy. A very careful series of experiments, both physiological and clinical, enabled them to indicate its therapeutic qualities with a marked degree of accuracy. With the other members of the aromatic series it was found to possess antiseptic, antipyretic, and analgesic properties, and they also pointed out that its action on the nervous system should make it of value in the treatment of many functional diseases. It was as an analgesic that they particularly advocated its use; the addition of the methyl atom to acetanilide had intensified this action without affecting its antipyretic properties, but it was found that a dose large enough to produce antipyresis, was accompanied by such alarming toxic symptoms that this use could not be considered. They advocated its employment in headache, migraine, neuralgia, neuroses of the viscera, the pains of locomotor ataxia, and in all non-febrile affections accompanied by pain. It was thought to be the most serviceable organic compound yet obtained for this purpose. It proved quite as active and certain as antipyrine, and yet never produced any disturbance of the digestive organs, never gave rise to any rash, nor had they found it accompanied by any distressing symptoms in the cases in which they had used it to relieve pain. It was found to relieve pain by producing insensibility without in any way affecting tactile sensibility or causing any other noticeable change in the condition of the patient. The dose they advised

was from four to six grains (0.25 to 0.40 gramme) in a single dose, or from six to eleven and a half grains (0.40 to 0.75 gramme) in the twenty-four hours.

Following this highly laudatory introduction, the use of the drug became very general, and the reports that followed were chiefly in accord with the statements of Dujardin-Beaumetz and Bardet; but it was also found that toxic symptoms frequently followed its use and that its employment was not without danger.

In Great Britain the notice of the profession was particularly directed to the value of this remedy by Professor Fraser, of Edinburgh,[1] who gave the results of his experience with it in the Royal Infirmary. The remarkable point in Professor Fraser's paper was the smallness of the dose and the success that followed its use in such quantities. The usual dose was half a grain in spirituous solution, repeated three or four times a day, according to the return of the pain. In some cases it was increased to one and two grains, and in a few instances four grains were given; the largest quantity given was fourteen grains during the twenty-four hours. In the cases of neuralgia and angina half-grain doses would relieve the pain in ten or fifteen minutes, and in one hour there would be perfect ease, which lasted from three to nine or ten hours, and in many instances a complete cure was obtained. In sciatica and locomotor ataxia one and two grains secured the same freedom from suffering. In cancerous disease and in the pain accompanying an aneurism the success was less marked, and it was in these cases that the larger doses were given. Dr. Fraser considers that the smaller dose is the proper method of administering the drug, and that all its virtues may be as readily secured as with the larger doses. When given in this way, there is not the slightest danger of any unfavorable symptoms, as in none of his cases did any such occur. He considers methylacetanilide to be an analgesic of much value, not so powerful as opium, but devoid of any of the latter's disturbing influence on the system and free from any danger. The following table, arranged by Dr. Fraser, shows at a glance the diseases in which he used this remedy and the successes and failures in each class of cases:

Disease.	Number of observations.	Successful.	Unsuccessful or doubtful.
Facial neuralgia	8	8	..
Sciatica	10	9	1
Herpetic neuralgia	10	9	1
Neuralgia of arm, in hemiplegia	11	11	..
Locomotor ataxia, first case	2	2	..
Locomotor ataxia, second case	1	1	..
Toothache, first case	2	2	..
Toothache, second case	2	2	..
Toothache, third case	2	2	..
Toothache, fourth case	2	.	2
Cardiac angina	2	2	..
Pleuritic pain, first case	1	.	1
Pleuritic pain, second case	4	4	..
Rheumatic synovitis	4	4	..
Blennorrhagic rheumatism	2	1	1
Gastric pain, cancer	2	2	.
Gastric pain, catarrh and cicatrized ulcer	4	2	2
Cancer in abdomen	10	6	4
Carcinoma of liver	2		2
Aneurism of aorta	4		4
Lumbar abscess	3		3

Following Dr. Fraser's paper came a number of reports of successful results with half- and one-grain doses, by Drs. Herschell,[2] Farrar,[2] Holden,[3] Maloney,[4] and many others. In these cases there was the usual success in pains of a purely neurotic character, and less favorable effects where it was due to organic disease or mechanical causes. It was found to be of greatest service in spare persons of a nervous temperament, and those subject to neurotic derangements. Contrary to the views of Dujardin-Beaumetz, it proved to be of much service in certain febrile troubles, particularly the headache and neuralgia of the epidemic of influenza, but in such cases it was inferior to the other new antipyretics, antipyrine and acetanilide.

The small doses recommended by Dr. Fraser, however, were not accepted generally. On the continent the doses of four to six grains were more frequently given; in England it was often found necessary to increase the dose to this amount, and many from its first use had adopted the larger doses of Dujardin-Beaumetz. Many reports of its complete failure were also made, but it has been very generally accepted as having useful analgesic properties, and promises to remain as a permanent addition to our armamentarium.

Exalgine has been used with equally favorable results in infantile troubles. Dr. Moncorvo [5] publishes his experience of its use in twenty-one cases of children ranging from one to twelve years of age, in which it was given for the relief of pain. He considers it a very useful agent. It was well borne in every case, no unfavorable symptoms being ever noticed. The dose commenced with was three-fourths of a grain, increased in some cases to five grains. In one case choreic symptoms were present and were improved.

Its use in chorea has been reported upon by Dr. Hugo Lowenthal.[6] Thirty-five cases were treated with doses of three grains, usually three times a day, never exceeding fifteen grains in the twenty-four hours. The effects were very satisfactory. The mild cases were cured quickly, but the more severe ones were less influenced and required more time. The beneficial effects of the treatment were most marked in the cases in which it was given early in the course of the disease, in two cases a cure being effected in eight days. A favorable influence over the mental state was also noticed; the fear and nervousness were lessened and the intelligence brightened. In some of the cases in which it was administered for a prolonged period, nausea, vertigo, headache, and other distressing symptoms were noticed.

Unfortunately the occurrence of toxic symptoms are not infrequent. No fatal termination has yet been reported, but the condition of the patient becomes very alarming both to the friends and to the physician. The toxic disturbances, however, are far in advance of its fatal dose. Experiments on animals have shown that the lethal quantity is seven and a half grains for each two pounds of the weight of the animal, and three grains, it has been found, will give rise to severe symptoms. The poisoning arises from the action of the drug on the nervous centres as well as from the alteration that occurs in the condition of the blood. The changes in the blood are the same as are produced by all aniline compounds, by which the hæmoglobin is altered into methæmoglobin and the function of oxidation interfered with. The approach of the toxic action is noticed by a sense of fulness in the head, a constriction and oppression of the chest, dyspnœa, vertigo, dizziness, numbness, disturbances of vision. This is followed by a rapid pulse, shallow respiration, and all the sensations of death with symptoms of asphyxia and collapse. Unconsciousness is common in the severe cases of poisoning; convulsions do not so frequently occur. Generally, very large quantities are given before any ill effects are noticed. In one instance [7] the drug was continued for seventeen days, in gradually increasing doses, and during the last seven days eighteen grains were administered daily. In another case [8] thirty-six grains were given within nine hours, and in another,[9] twenty-four grains within two hours. The ill effects of the drug generally follow the prolonged use of the drug, or the administration of large doses, but in some instances very small doses have produced very alarming effects. An instance [10] is reported in which two doses of three grains caused all the serious symptoms of poisoning, and another instance in which two doses of five grains were given with the same effect. A remarkable [11] case is reported in which, in an adult, two doses of one and two grains, respectively, produced most profound prostration. The symptoms came on about an hour after the last dose, while the patient was sitting at a table engaged in a game of cards. He first complained

of a fulness in the head and suddenly fell prostrate, unable to speak or move, and gasping for breath. A second attack took place in about an hour, and the oppression and dyspnœa continued for several hours. Very different to these cases are those in which very large quantities have been given without evil consequences. Dr. Churton[12] reports two such cases. In the refilling of a bottle of medicine a mistake was made by which a solution was prepared of one grain to a drachm, instead of one grain to the ounce. The medicine was given as usual, four grains instead of half a grain being contained in each dose. This was continued for several days, and during the last twenty-four hours before the mistake was detected the patient was given forty grains. The pulse and respiration were rapid, and the patient complained of a burning sensation in the stomach, but no other effects were noticed. The second patient was given twenty-four grains from the same preparation without producing any other effect than slight vertigo and a sense of being "dazed," which caused her to walk unsteadily. The quality of the drug is vouched for, as it was given to a number of patients with satisfactory results, and small doses were again given to the first patient, and its analgesic action secured.

The quality of the drug undoubtedly affects its action, and in many instances explains the varying results that follow its use, but certain conditions of the system must exercise a decided influence, probably by promoting the decomposition of the drug and the formation of more toxic compounds. Mr. Bokenham[7] dwells upon this point in his remarks upon two cases of poisoning and suggests that some condition of the blood preceding menstruation may assist this reaction. The activity of the action is also influenced by the time of its ingestion. Professor Fraser and others, who find benefit in the small doses, always recommend that it should be given on an empty stomach, while those who use the larger doses advise it to be given after meals, and others still have remarked that the toxic symptoms arise when it has been given before meals. In the majority of cases the toxic symptoms pass away without requiring any assistance, but when the depression and dyspnœa are severe, stimulating remedies must be used. Alcohol has been resorted to in most of the cases of poisoning with apparent benefit, and hypodermic injections of ether have also been employed. In the cases reported by Dr. Jones[7] marked relief was secured by the use of strychnine in addition to the stimulants. Two minims of the liquor strychniæ were given hypodermically and ten minims of tincture of digitalis by the mouth. In these cases the inhalation of nitrite of amyl and $\frac{1}{100}$-grain doses of nitro-glycerine increased the cyanosis, showing that the arterial as well as the venous blood was altered.

The following conclusions have been arrived at by Marandon de Montyel[13] from clinical observations on patients in whom its use had been pushed to its physiological limits:—It has no influence on digestion. If the stomach is empty it causes an increased flow of saliva, a bitter taste, and a sense of tightness about the epigastrium. The pulse, respiration, and temperature are lessened in patients without convulsive tendencies. Vertigo, flashes of light and ringing in the ears are frequent. A local or general cyanotic surface, sensations of cold, numbness, and formication, are prominent symptoms. Its action is prompt and recovered from promptly, the brain being the first organ affected and the first to recover. When administered after meals its physiological action is less marked. *Beaumont Small.*

EXAMINER, MEDICAL. The medical examiner system of Massachusetts, enacted in place of the coroner's inquest system which was abolished in 1877, has now (1893) been in successful operation for nearly sixteen years, and it is safe to say that no return to the coroner system will ever be made in Massachusetts. The law is quoted in full, and its advantages are fully stated in the second volume of this work.

The following statistics relative to the operation of this law are quoted from the registration reports of Massachusetts, for the years 1885 to 1891 inclusive:

TOTAL DEATHS, AND DEATHS BY SEXES, INVESTIGATED UNDER THE MEDICAL EXAMINER LAWS IN MASSACHUSETTS, 1885–1891.

YEARS.	SEX.						TOTALS.*
	Males.	Per cent.	Females.	Per cent.	Unspecified.	Per cent.	
1885.....	973	76.1	286	22.4	19	1.5	1,278
1886.....	1,027	74.5	319	23.2	32	2.3	1,378
1887.....	1,191	76.5	350	22.5	15	1.0	1,556
1888.....	1,261	76.4	373	22.6	17	1.0	1,651
1889.....	1,253	75.8	388	23.4	13	0.8	1,654
1890.....	1,303	73.5	449	25.3	21	1.2	1,773
1891.....	1,362	74.0	457	24.8	21	1.2	1,840
Totals.....	8,370	75 2	2,622	23.6	138	1.2	11,130

In the following table the same deaths are classified by the modes of death:

RECAPITULATION.

YEARS.	HOMICIDE.		SUICIDE.		ACCIDENT OR NEGLIGENCE.		NATURAL AND UNKNOWN CAUSES, INCLUDING ALCOHOLISM.		TOTALS.
	Number.	Per cent.	Number.	Per cent.	Number.	Per cent.	Number.	Per cent.	
1885..	45	3.52	181	14.17	567	44.37	485	37.94	1,278
1886..	47	3.41	157	11.38	678	49.17	496	36.00	1,378
1887..	52	3.34	173	11.12	748	48.07	583	37.47	1,556

1889..	51	3.08	199	12.03	792	47.89	612	37.00	1,654
1890..	35	1.97	196	11.05	862	48.62	680	38.36	1,773
1891..	60	3.26	187	10.16	866	47.07	727	39.51	1,840
Totals	342	3.07	1,283	11.53	5,298	47.60	4,207	37.80	11,130

In the following table are presented the number of autopsies, the total expenses incurred in each year, and the average cost of investigation of each case, so far as the medical examinations were concerned. The expenses of 1891 had not been made up at the time of writ-

Year.	Total number of cases examined.	Autopsies.	Total expenses.	Average expense of each case.
1885.....	1,278	165	$16,322.54	$12.77
1886.....	1,378	202	18,024.22	13.08
1887.....	1,556	188	18,626.26	11.97
1888.....	1,651	219	19,611.53	11.88
1889.....	1,654	216	19,489.69	11.78
1890.....	1,773	206	20,710.63	11.68

ing, but it is safe to say that the average expense of each case was still further reduced as compared with that of previous years.

After the system was inaugurated, and had been in successful operation for three years, a careful inquiry of

the expenses under the old coroner laws, and also under the present system showed a decided lessening in the expenses, the two chief causes of the reduction being the abolition of the useless coroner's jury, and the diminution in the number of inquests.

It is a sufficient comment upon this law that more than eighteen thousand cases of sudden, suspicious, and violent deaths have been investigated under its authority, and in a far more satisfactory, intelligent, and economical manner than could have been possible under the old *régime*. *Samuel W. Abbott.*

EXMOUTH. A popular sea-bathing resort in Devonshire, England. Exmouth is ten miles from Exeter and occupies a fine situation on the Devon coast. The beach is remarkably good. The climate is moderately warm and equable, although the place is not so well sheltered from winds as Budleigh Salton, some five miles distant. There are fine coast and inland views, and the usual facilities for seaside enjoyments. Season, June to September. The place, though foggy, is healthy.
Edmund C. Wendt.

EXPECTORANTS. The well-known action of oil of turpentine upon the bronchial mucous membrane seems to be possessed by its derivatives, terpin hydrate, terebene, and terpinol. Terpin hydrate was recommended in 1885 as a very efficient agent in chronic bronchial catarrh, and preferable to oil of turpentine on account of the absence of unpleasant physical properties. Since then it has been employed by a large number of clinicians, and has been found to be a reliable remedy in bronchitis and whooping-cough.

Terpin Hydrate, $C_{10}H_{16}3H_2O$, is a hydrate of oil of turpentine that often forms when the oil is in contact with a small quantity of water for some time. On a large scale it is obtained by mixing oil of turpentine with alcohol and nitric acid. It is in the form of large colorless crystals, having no odor and only a very slight aromatic taste. It dissolves in 250 parts of water at 15° C., in 32 parts of boiling water, and in 10 parts of alcohol.

Terpin hydrate was introduced by R. Lepine, of Lyon, as an effective remedy for chronic bronchitis. He had used it in several hundred cases, and had observed that doses of 0.2 to 0.6 (three to nine grains) daily rendered the sputa less tenacious and more copious, and facilitated expectoration. In cases of bronchorrhœa larger doses, 1.5 daily (twenty-two grains), lessened the quantity of sputum. Such doses also increased the action of the kidneys, but, when these organs were normal, never caused albuminuria or hæmaturia.

The observations of Lepine have been corroborated by a number of clinicians in large hospitals. Thus Germain Sée found terpin hydrate very effective in catarrhal affections of the respiratory mucous membrane, the morbid secretion gradually diminishing under its prolonged use. In catarrhal forms of phthisis, he observed that the mucopurulent secretion lessened and often entirely ceased. He employed it also to arrest the hæmoptysis of the early stage of phthisis, and held it to act more rapidly than ergotin.

Dr. Lazarus, of Berlin, employed terpin hydrate in a large number of cases of bronchitis with good results. Marked effects, however, occurred only when he used large doses, from twenty to thirty grains daily. To avoid unpleasant effects on the digestive organs, the medicine was given in pills and taken during meals. He regards as the special indication for terpin hydrate great irritability of the bronchial mucous membrane with very scanty or very tenacious secretion. The effect observed was an increase of the sputum, which became more fluid and was easily expectorated. Usually the catarrhal symptoms vanished in from eight to fourteen days.

Dr. Manasse, of Berlin, used terpin hydrate for several years in a large number of cases of bronchitis. When small doses were given no very striking effects resulted; but large doses, from thirty to forty-five grains daily, proved decidedly efficient in chronic bronchial catarrh. In no case, although hundreds were treated, did any unpleasant incidental effects occur. He found terpin hydrate very useful also in whooping-cough, of which he treated forty-one cases, varying in age from nine months to twelve years. Every case was carefully observed, the frequency and severity of the paroxysms being noted daily. To children under one year of age he sometimes gave as much as 1.5 (twenty-two grains) daily, and never observed any injurious action on the digestive or urinary apparatus. And in no case, when 2.5 to 3.0 daily were given to older children, did the urine become albuminous or bloody. As a rule, in four or five days the paroxysms were less numerous and always less severe. The bronchial catarrh, which was present in most cases, diminished more rapidly than usual, and finally disappeared entirely. All the cases treated with terpin hydrate recovered. The medicine was given in the form of powder:

℞. Terpini hydrati..... 5.0–10.0
Div. in part. æqual. No. x. S.: One powder three times daily.

The following formulæ have been recommended:

℞. Terpini hydrat 3.0
Saech. alb.,
Mucil. acaciæ .....āā q. s.
M. ft. pil. No. 30. S.: One to four pills three times daily.

℞. Terpin hydrat 2.0
Spiritus,
Aq. dest.,
Syr. menthæ pip.....āā 50.0
M. S.: One tablespoonful from three to six times daily.

Codeine.—Codeine has recently come into use as a means of allaying cough. According to numerous reports, it is generally as effectual as morphine or the preparations of opium. Often it has been observed that the cough of mild forms of bronchitis ceased in a few days. But its principal advantage is that it does not depress the functions of the alimentary canal. The use of morphine is usually followed by a diminution of appetite, and often by constipation. Codeine, while it allays the cough, does not interfere with the appetite, or with the normal action of the bowels. This has been especially observed in phthisis, in which codeine was found to mitigate the cough without lessening the desire for food. When, to test the difference in action, Dover's powder was given to patients that had been taking codeine, the appetite, which had improved under the use of codeine, diminished again, showing the decided superiority of codeine. It has been found to be very useful in the bronchitis of children, and, in appropriate doses, has been given to infants, without any unpleasant effects.

Codeine should, therefore, be preferred to morphine in all cases of severe cough in which it is necessary to maintain a good appetite, as in bronchial catarrhs complicating chronic wasting diseases, in children, and in persons subject to constipation. Especially, should codeine be preferred to morphine to relieve the cough of phthisis; for if the means used to mitigate this tormenting symptom interfere with digestion and nutrition, little hope of saving life can be entertained.

The salts of codeine commonly used are the sulphate, phosphate, and hydrochloride. They all readily dissolve in water, and are usually prescribed in aqueous solution with a small quantity of syrup, or together with sugar, in the form of powder. The dose for adults is one-fourth to three fourths of a grain; for infants, one-sixtieth of a grain; and for children three or four years of age, one-fifteenth to one-tenth of a grain, from three to five times daily. *Samuel Nickles.*

EYE DISEASES, NOMENCLATURE AND STATISTICS OF. No successful effort has been recently made to decide upon a complete and scientific nomenclature of eye diseases, and in the present state of ophthalmology it would be difficult, if not impossible, to do so. When

such action is taken, it must be by some representative scientific body, as the American Ophthalmological Society, not by an individual. The nomenclature presented below is, strictly speaking, neither complete nor scientific, but practical; for it covers and enables us to study the statistics—to us the most important side of the question—of upward of three hundred thousand eye patients, as reported in the leading eye hospitals in this country. It was prepared from the lists of diseases as they appeared in the twenty-four annual reports of the ten different eye hospitals enumerated at the close of this article. Each disease was recorded, and when the list was complete, it was placed under its proper heading for final use.

The statistical portion is based upon a study of the 301,744 cases of eye disease embodied in the reports above referred to.

The tables explain themselves. Each disease is credited in the first column with the number of cases of such affection found in the grand total of 301,744 recorded cases, while the second column shows the relative frequency of each such affection, this frequency being expressed in numbers which indicate how often the disease is encountered in 1,000 of the cases which form the basis of this inquiry. When the proportion is materially less than one in a thousand, no entry whatever is made in the second column; and, furthermore, these entries are made only in round numbers.

	Total number of cases.	Number of cases of such disease in 1,000 cases of eye disease in general.

James Lancelot Minor.

EYE SYMPTOMS, DIAGNOSTIC SIGNIFICANCE OF; AND ETIOLOGY OF EYE DISEASES. The study of the causes of eye affections is not only important with reference to the treatment of these diseases, but often proves of service in the practice of clinical medicine in general. The eyes are so often involved in consequence of derangements of other organs that ocular symptoms are not rarely the earliest signs of internal diseases. Thus, kidney disease and diabetes are sometimes recognized by the oculist before the necessity for the family physician has been felt. Syphilis, acquired or congenital, may reveal itself for a time in the eye only, and various diseases of the central nervous system are first seen in their incipiency by the ophthalmic specialist or require his methods for their correct localization. In order, therefore, that this article shall be of full value to the general reader, it must involve the diagnostic significance of mere symptoms as well as the etiology of ocular lesions.

Affections of the eyes, like diseases in general, may be classified etiologically as either *primary diseases*, in which the derangement is directly due to some cause from the outer world, or *secondary affections*, which result from a pre-existing anomaly in some other part of the system. While this distinction must be kept in view for the purpose of research, our knowledge is not yet sufficiently complete in every instance to maintain it in practice. In the case of the eye, perhaps more than in the case of any other organ, there occur, moreover, affections which may be termed intermediate between primary and secondary diseases. For there are many eye troubles which are primary in the sense that they are caused by infection, an occurrence originating in the outer world, but secondary inasmuch as such infection will take place only if the germs have previously gained a foothold in some other part of the economy.

The frequent occurrence of eye symptoms and lesions in consequence of other diseases depends on the exceptionally intimate connection between the visual organ and other parts of the economy, as well as on the complicated and hence delicate histological structure of the eye. Through the general circulation germs and poisons can reach the eye, while the nutrition of the ocular tissues reacts readily to changes in the blood or the walls of the vessels. Infections gain access through the extensive lymphatic connections, through fissures in the walls of the orbit, or along the channel of the tear-duct. The nutritive integrity of the optic nerve is influenced by morbid processes in many parts of the brain or even spinal cord, and derangements in the co-ordination of the extrinsic and intrinsic muscles of the eye indicate in the most sensitive manner any disease in the large central area from which their nerves originate.

The etiological dependence of any eye affection on a given anomaly in some other part of the body may be proven in various ways. It is suggested by the coincidence or sequence of the two disturbances, and the probability of a relationship increases with the frequency of the observations. As some forms of eye trouble may have different modes of origin in different cases, the occasional occurrence of an eye disease in the course of other disturbances, but which may also be seen at times without the coexistence of the latter, does not exclude a relationship. But if a characteristic ocular lesion is seen only in connection with certain internal diseases, as the "albuminuric" form of retinitis in kidney diseases, the relationship is clearly established.

The etiological proof is also furnished whenever a morbid process can be watched clinically or traced pathologically in its encroachment from some adjacent struct-

ure into the orbit. In other instances the dependence of ocular disturbances upon pre-existing other anomalies may be shown by the influence exerted upon them by the treatment of the suspected condition. Unless such influence, however, is very striking, and the prognosis of the eye-trouble is fully known, this mode of reasoning is liable to errors. The most satisfactory proof of the relation of any morbid occurrence to any eye anomaly is only furnished by the experimental production of the latter. But this method has been as yet but little pursued.

For reasons of convenience the plan of this article will be to detail the etiological significance of the various eye affections from the standpoint of the oculist, while a survey of the eye symptoms and lesions to which any specified internal disease may give rise can be obtained from the classified index.*

I. Lachrymal Apparatus.

1. The lachrymal gland—very rarely the seat of disease—may undergo chronic inflammatory enlargement in acquired *syphilis*. A few observations are on record of swelling of the gland during an attack of *mumps*, and a similar subacute inflammation has also been interpreted as a vicarious form of mumps, the diagnosis being based on the existence of mumps in others in the same dwelling. In *leucocythæmia* the tumefaction characteristic of that disease may also, though rarely, occur in the lachrymal gland.

2. Lachrymation, or the overflow of tears, indicates over-activity of the gland, but not necessarily impaired drainage of tears, as is shown by ordinary crying. It occurs during the course of all irritating forms of disease of the anterior parts of the eye. It may also result, though less frequently, from eye-strain. In some instances it depends on *irritability* of the *mucous lining of the nose*, due to sharp crests on the nasal septum or to enlarged turbinated bodies.

Obstruction of the tear-passages is not necessarily accompanied by steady lachrymation, but if in this condition a flow of tears is started by eye-strain or irritation by wind and dust, the tears can only escape by running over the lower lid. In about one-half the cases of lachrymal stricture the disease of the tear-passage seems to be by itself the cause of continuous overaction of the tear-gland.

3. Obstruction of the lachrymal canaliculi may result from extension of conjunctival inflammations. Strictures just above or in the lachrymal sac and suppurative inflammation of the sac, dacryocystitis, are usually, if not always, of *nasal origin*. The suppuration of the sac in the latter form is, of course, the direct result of the action of pus microbes. It is not merely the more serious forms of nasal disease; like syphilitic ulceration, lupus, and polypi which lead to disease of the lachrymal duct, but more frequently even transient acute catarrh, especially in connection with stenosis of one or both sides of the nose. Quite often a one-sided lachrymal disease corresponds to the narrower side of the nose. In a large proportion of cases of lachrymal obstruction permanent anomalies can be found in the nose, such as enlargement of the inferior turbinated body and malformation of or crests on the septum. The extension of infection from the sac to the skin covering it (phlegmonous dacryocystitis) and the subsequent formation of a lachrymal fistula can sometimes be traced to the influence of an acute nasal catarrh.

Dacryocystitis is an occasional occurrence during small-pox.

II. Lids.

1. The various forms of diseases of the skin of the lids, eczema, lichen, acne rosacea, and favus, are, as a rule but an extension of the same affection on adjacent parts of the facial skin, and their causes, so far as they are known, are also the same. Herpes, more common in the vicinity than on the lid itself, may, however, also involve the lids, or even be limited to them (herpes zoster ophthalmicus). The accompanying neuralgia and local anæsthesia show that it is due to *disease of the fifth nerve*.

Globules attached to the cilia like beads on a string are the eggs of lice. Direct infection leads occasionally to a *vaccinia* pustule on the lid. *Chancre* of the lid has also been observed. Of secondary *syphilitic* eruptions condylomata are more common than ulcerating papules. Ulceration may be due to *lupus vulgaris, lupus erythematosus, epithelioma*, or *rodent ulcer*.

Multiple tumors of the lids have been seen in *leucocythæmia*.

Ecchymoses, most commonly of traumatic origin, occur without trauma in *scurvy* and in *purpura hæmorrhagica*.

2. Œdema of the lids, if bilateral, is an early sign of *renal disease* and of *arsenical* poisoning. Mere puffiness, not pitting on pressure, has not this significance. It is not uncommon in irritative *nasal disease*, especially *hay fever*, and it may also occur with some slight forms of conjunctivitis, or as the result of any inflammatory action in cornea, sclera, or iris. *Irritation* of a *hypersensitive nasal membrane* causes at times a sudden transient, one-sided, or bilateral œdema of the skin of the lids, sometimes resembling urticaria, sometimes more like erysipelas. Frequent repetition of such attacks leaves the lids either dusky or permanently puffy. Genuine erysipelas, *i.e.*, the infection by the streptococcus, differs from these pseudo-erysipelatous attacks by its accompanying fever and its progressive tendency. A condition which a hasty observer can mistake for erysipelas is the inflammatory œdema of the lower lid induced by the extension of phlegmonous infection from the lachrymal sac to the surrounding skin.

3. The only disease of the tarsus known etiologically is the chronic inflammatory hypertrophy of (late) *syphilis*. In some instances of a similar disease, however, syphilis is not present.

4. Chalazion, the inflammatory enlargement of a Meibomian gland, is perhaps in some, probably rare, instances of *tubercular* origin, as Tangl [1] has found the bacillus tuberculosis, and Kœnigshoefer and Maschke [2] have observed the tuberculin reaction, in such cases. In the majority of cases this harmless tumor is not tubercular, according to clinical experiences as well as bacteriological tests by Weiss,[3] and Deutschmann.[4]

5. Blepharitis, inflammation of the edge of the lid, appears in the squamous, interstitial, and ulcerative forms. In the latter the ulceration is due to pus microbes, but whether the other forms depend on parasites is unknown. There are, however, four conditions, one or more of which often maintain the blepharitis, or cause it to relapse after the cessation of local treatment. These are, (*a*) eye-strain (hypermetropia or astigmatism); (*b*) insufficient length of the skin of the upper lid [5] causing gaping of the lids during sleep; (*c*) obstruction of the tear-passages, and (*d*) nasal disease, sometimes in the form of stenosis, sometimes in that of atrophic rhinitis. Some of the alleged factors stated in the books as causes of blepharitis, viz., scrofula and unhealthy surroundings, are not confirmed by experience in actual practice.

Blepharitis is a very common sequence of *measles*.

6. Of the distortion of the lids, ectropion is mostly due to cicatricial shrinkage of the skin after burns or lupus, sometimes also to hypertrophic swelling of the conjunctiva from long-standing irritation by the tears in consequence of lachrymal obstruction, especially in elderly people. A characteristic form of ectropion is that due to cicatricial adhesion of the skin to the margin of the orbit from caries of the orbital rim in scrofulous children. Entropion is most commonly the result of conjunctival shrinkage after trachoma. Inversion of the cilia —trichiasis—is generally due to the same cause; sometimes to long-continued interstitial blepharitis. Partial turning in of the lashes—distichiasis—may occur congen-

* The writer has not aimed at absolute completeness in the present place, and will therefore not include the etiological bearing of rare eye diseases based on very exceptional occurrences or on deductions supported by insufficient evidence. On the other hand, it would be superfluous to merely tabulate those eye-affections the etiology of which is not known. As there is a reference at the end of the article to the general literature of the subject, the quotations in the text are limited to the more important or recent researches, or such as are not included in the references appended.

itally. In old people with relaxed skin the puffiness engendered by tears under an eye-bandage (after operations), or accompanying irritative diseases of the eye, may cause transient spasmodic entropion.

7. Anomalies of the muscles of the eyelids are always of nervous not of muscular origin. Spasm of the orbicularis muscle is either tonic or clonic. The former accompanies to a variable degree all irritative diseases of the anterior part of the eyeball which cause photophobia; it may be due also to foreign bodies in the conjunctival sac. The most distressing form of tonic blepharospasm is the spasm sometimes persisting in neurotic patients after the original ocular disease itself has disappeared. In some instances its continuance depends on the existence of tender spots (neuritis ?) in the distribution of sensory nerves of the face around the orbit. This is at any rate the interpretation of the curative results obtained by Von Graefe and others by neurotomy of the supra-orbital and other nerves.

Clonic blepharospasm appears in various forms. Mere fibrillary twitching of a transient character occurs from eye strain and a variety of influences, like overwork, insufficient sleep, etc. Fibrillary twitching of the orbicularis, as well as the adjoining facial muscles, generally one-sided, the tic convulsif of neurologists, is a serious and often incurable disease of the facial nerve. Its pathology is generally not known; in certain not common instances it is a reflex which may start from *eye strain*[6] or *conjunctival irritation* (personal observation), from *nasal anomalies*,[7] or from *defective teeth*.

Spasmodic winking of the lids is but a localized form of *chorea* and quite often the movements, at first limited to the lids, extend later on to other facial muscles. The subjects usually have a neurotic disposition, revealed by the family history or their own neurotic antecedents or subsequent history.

Often a reflex origin can be detected, either eye strain (H. or As.) or follicular hypertrophy of the conjunctiva or nasal anomalies, and the correction of these defects may prove the reflex character. It must not be overlooked that the disposition to such exaggerated reflexes is augmented by all influences which lower the resisting power of the organism, as close confinement, overwork, disturbances of digestion, anæmia, etc.

Lagophthalmus, the inability to close the eyelids, is the result of *paralysis* of the *facial nerve* and may depend on a peripheral facial neuritis (sometimes from disease of the ear or the temporal bone) or on an affection of the central nucleus of the facial nerve.

Ptosis, the (partial or complete) inability to open the lids, is either due to excessive thickness of the lids (after trachoma or from subcutaneous tumor) or to lesion of the third nerve. A slight form is not rarely congenital, probably from ante-natal nuclear disease (often involving the recti muscles as well). The significance of recent paralysis of the motor oculi can be treated to better advantage in connection with paralysis of the ocular muscles.

The lid aperture is of more than average width (but without muscular weakness) in high *myopia* and in exophthalmus, especially in *exophthalmic goître*. Characteristic of the latter trouble is Von Graefe's sign. On looking downward the upper lid normally follows the movement of the eyeball, while in *exophthalmic goître* the upper lid lags behind, and with extreme downward version of the eye more than the usual amount of the ocular surface is exposed.

III. Conjunctiva.

1. Conjunctival hemorrhages occur in purpura, but also from violent cough, especially whooping-cough, and other violent exertion, as in epileptic attacks or from slight trauma. They have been considered diagnostic of death from asphyxia. If they occur without sufficient provocation in elderly people they indicate vascular disease and danger of apoplexy. The conjunctiva of the eyeball presents the best conditions for the observation of *jaundice*.

Sudden chemosis of the conjunctiva indicates in some instances that a *purulent inflammation* of the *cerebral meninges* is encroaching upon the orbital contents.

2. Chronic conjunctival hyperæmia (often associated with blepharitis) is indicative of *eye-strain*, *lachrymal obstruction*, or *nasal stenosis*. Chronic catarrh is often a secondary infection of a conjunctiva habitually congested. It may depend in other cases on *skin diseases*, as eczema of the lid, or of parts adjoining it, or it may be the remnant of a former acute conjunctivitis. Acute follicular conjunctivitis leaves in some persons a permanent enlargement of the adenoid tissue which at times becomes complicated with catarrhal inflammation, but without it, too, may constitute an easily overlooked source of irritation. It is also stated (Foerster) that a chronic catarrhal conjunctivitis of very tedious course may be kept up by masturbation.

3. Acute conjunctivitis is probably always an infection, excepting the form due to the influence of the ultra-violet rays of the electric arc light.[8] The severe but transient form, which when epidemic is popularly known as "pink-eye," has been traced by Weeks[9] to the invasion by a characteristic small bacillus. There are probably various micro-organisms capable of causing contagious conjunctivitis. Other forms are apparently due to common saprophytic bacteria, which are frequently found in the conjunctiva and always on the skin. Whenever the conjunctiva is wounded or chemically irritated, catarrhal infection commonly follows. Contagious, and hence clearly of parasitic origin, is the form of acute conjunctivitis which in many of the persons affected causes follicular enlargement and may even resemble trachoma (although different in its course).

A rather rebellious form of conjunctivitis, usually not severe, but sometimes leading to considerable hypertrophy, is at times observed in connection with *purulent rhinitis*. Transient conjunctivitis is also a regular symptom of *measles* during the initial period. Conjunctivitis with hemorrhages has been observed in attacks of *influenza*.

The most violent conjunctivitis is that caused by the *gonorrhœal* virus, usually transferred by towels, hands, etc. The *gonococcus* is likewise the cause of all cases of characteristic conjunctivitis neonatorum. The infection occurs in the vagina and leads to visible inflammation on the third day after birth. If the conjunctivitis appears before this date the case was one of protracted birth with early rupture of the membranes. The proof of the origin of this scourge of infants is furnished both by the regular presence of the gonococcus in the secretion as well as by its absolute prevention by means of nitrate of silver (two per cent.) dropped into the conjunctival sac at birth (Credé's method). The insignificant conjunctivitis of babies, of irregular occurrence and of a duration of but a few days, is usually not caused by the gonococcus. Whether this parasite ever occurs in a form of diminished virulence after long existence in the maternal passages is not unlikely on the strength of clinical evidence, but not yet proven. An entirely different, mild, not dangerous, but persistent form of conjunctivitis, not due to the local action of the gonorrhœal virus, but occurring during the course of gonorrhœa, has been described by Haltenhoff. Diphtheritic conjunctivitis is caused by the bacillus characteristic of *diphtheria*, but the conditions necessary for its invasion usually escape analysis, as the patients are generally free from diphtheria in other parts of the system. It has been, however, produced by the coughing of diphtheritic patients hurling the virus into the eye of the attendant. Whether croupous conjunctivitis is due to the same parasite is not yet known.

Trachoma or granular conjunctivitis is a disease so unmistakably contagious that there can be no doubt as to its parasitic origin. Yet none of the attempts made by Sattler, Michel, and various others to identify the virus (as a micrococcus) have led to satisfactory or convincing results. The disease has often occurred in an epidemic form in former times in armies, schools, and other institutions. Cleanliness and isolation have within recent years diminished the frequency of such epidemics.

In its non-epidemic form the disease is not apt to spread to others as long as care is taken in the use of towels, handkerchiefs, etc. Hence it is evident that unsanitary surroundings and poverty favor its spreading. A factor, which the writer believes has not received due attention, seems to account for the variable contagiousness. Observation shows that the disease is, or at least can be, transferred by means of the conjunctival secretion. Sporadic cases, however, of pure trachoma are often not accompanied by any secretion whatsoever, or show pus only during periods of aggravation. Epidemic trachoma, on the other hand, furnishes copious conjunctival pus. It seems, therefore, not unlikely that the more virulent and contagious forms of granular lids represent a mixed infection by the trachoma virus, associated with some microbe causing catarrhal inflammation.

Burnett has pointed out that the negro has nearly absolute immunity against trachoma. Chibret has likewise credited the Celtic races of Europe with being less prone to take the disease,[10] a statement which is not confirmed by the distribution of the disease in this country. Chibret has also called attention to the comparative immunity of localities of an altitude over two hundred metres, from which rule numerous exceptions, however, have been pointed out by others. Occasionally trachoma is limited to one eye. Whether the disease in these instances is etiologically different from ordinary bilateral trachoma is not known. The writer has observed the frequent coincidence of one-sided trachoma with one-sided nasal obstructive lesions.

Goldzieher [11] has described a disease resembling trachoma, but due to syphilis and curable by antisyphilitic treatment.

4. Xerosis, an inflammation with the occurrence of characteristic white, fatty-appearing spots on the conjunctiva, and often leading to corneal ulceration, or even necrosis, is a disease indicative of grave danger to life, and is observed mainly in ill-nourished infants. The disease is often accompanied by hemeralopia. Von Graefe originally described it as coincident with encephalitis, but Jastrowitz [12] has since shown that the lesions found in the brain, viz., fat-granules in the neuroglia cells, do not signify inflammatory, but simply degenerative change. Indeed, xerosis has been seen in the course of various exhausting diseases—typhus, small-pox, etc.

Jewezki [13] has seen the disease remarkably often among workmen in a glass furnace. In the xerotic patches Kuschbert and Neisser have found a pure culture of a characteristic bacillus. But while the existence of this bacillus has been confirmed, it has been shown by Fick, Weeks, and others, that it is but a common parasite of the normal conjunctival surface, and not peculiar to or causative of xerosis.

5. Tuberculosis of the conjunctiva may either result from extension of the same disease in the nasal cavity or from metastasis of tuberculosis of internal organs.

6. Pemphigus of the conjunctiva has been seen in connection with *pemphigus* of the skin. It may lead to partial or complete obliteration of the conjunctival sac by adhesion of the lids to the eyeball.

IV. Sclera.

Episcleritis occurs in some instances in persons of rheumatic or of gouty history and is often influenced by corresponding remedies (salicylates and antipyrin) in such a decisive manner that a rheumatic or—as the case may be—gouty origin is strongly suggested. In other instances, however, no such relationship can be demonstrated.

V. Cornea.

1. The superficial opacity of the cornea with new formation of vessels known as pannus is the result either of irritation by inverted eyelashes or of trachomatous disease of the lids. A circumscribed surface opacity with vascular connection is sometimes caused by a relatively bland foreign body (especially grain-husks) embedded in the cornea. Another form of superficial vascular keratitis beginning with circumscribed corneal exudations near the limbus, and of very persistent course, the writer has found associated with *hypertrophic rhinitis*.

2. Herpes vesicles limited to the cornea have been described by Horner as a not infrequent occurrence (together with herpes labialis) during the course of or after *inflammatory disease of the respiratory passages*.

3. Phlyctenular keratitis, usually considered indicative of infantile *scrofula*, is so often associated with, or preceded by, subacute *suppurative rhinitis* that a causative relation of the latter is strongly suggested. This form of rhinitis and consecutively corneal phlyctenulæ frequently follow *measles*. Attention has also been called to the frequent coincidence of head-lice and phlyctenulæ (rare in this country). On the other hand, both clinical sequence as well as therapeutic results show that *eczema* of or around the lids and ulcerative blepharitis may induce phlyctenular disease as well as even deeper corneal infiltration. The attempts to identify the alleged microorganism of phlyctenular keratitis (Burchardt) cannot be called satisfactory.

4. A superficial form of linear corneal infiltration (with loss of epithelium) assuming an arborescent shape has been referred by Kipp [14] to *malarial influence*, on account of the patient's history and the influence of quinine on this disease. But a similar form has been met with by Emmert in non-malarial cases, and termed by him keratitis dendritica. It has been seen more often following influenza during the recent epidemics. Another form of corneal disease, characterized by its name keratitis punctata superficialis, has also been described but very recently, and has been known to follow in the wake of influenza. Superficial corneal infiltrations, often leading to ulceration, depend often upon disease of the conjunctiva, especially trachoma, but also, though less frequently, on chronic catarrhal conjunctivitis with hypertrophy of the fold of the fornix. Another source of similar corneal disease is ulcerative blepharitis.

5. Inflammation of the substance proper of the cornea often occurs without assignable cause. A variety has been ascribed by Arlt to *rheumatic influence*, and is said to be characterized by the ground-glass appearance of the cornea, by epithelial abrasions, which sometimes lead to shallow ulceration, and by the indolent course. Recent observations (Berger) confirm the view as to the rheumatic origin of this form by the marked influence upon it of antipyrin and salicylates. A similar form of keratitis the writer has seen following herpes frontalis. The existence of a gouty keratitis in the form of small circumscribed interstitial opacities has been confirmed by Chevallereau by the chemical detection of uric acid in the opaque spot.

The most characteristic form of deep keratitis of extremely indolent course, usually affecting one eye ahead of the other and followed regularly by the formation of a very delicate but persistent net-work of vessels in, and not merely on the surface of, the cornea,[15] occurs in children or young persons with *hereditary syphilis*. Most observers agree that this disease is by itself diagnostic of inherited syphilis.

It has also been asserted that some forms of interstitial keratitis depend on carious teeth and yield only to the extraction of the latter (Galezowski).

A central interstitial keratitis, often with iritis, has been found by Chibret associated with neuralgia of the fifth nerve and apparently secondary to the latter trouble.

6. What is commonly called keratitis punctata, or keratitis postica, is not a disease of the cornea itself, but a deposit of clusters of cells on the posterior surface of Descemet's membrane in connection with the serous (or, much more rarely, the plastic) form of iritis, and also in certain acute attacks of circumscribed chorio-retinitis.[16]

7. Corneal ulceration is the result of local infection, and in those instances of spreading ulcer (ulcus serpens) which have been examined bacteriologically the pus-forming staphylococci and streptococci were found. As these micro-organisms are widely disseminated, they can easily gain access to any wound, or even scratch, by foreign bodies. The most virulent infection results from the presence of the pus of *dacryocystitis*. Where such

virulent pus is not present, it evidently requires special conditions, but imperfectly understood, for the occurrence of progressive infection. Some of these conditions are pre-existing disease of the conjunctiva, especially trachoma, lacerated wounds of the cornea, for instance, by sawdust blown into the eye, and an enfeebled state of the system, as on recovery from typhoid fever and other exhaustive diseases. *Variola* may cause corneal ulcers either by the extension of pustules localized on the cornea or by infiltration occurring at a later stage, which subsequently breaks down. Ulcers also occur, though not commonly, in *diabetic* patients. In *scrofulous* children some ulcers, of a very persistent character, give the characteristic reaction to tuberculin injections and heal under its use so promptly as to raise a suspicion as to their *tubercular* origin. But the presence of the tuberele bacillus has not yet been demonstrated.

8. Necrosis of the cornea—complete or partial—has been observed in consequence of invasion by mould fungus (aspergillus glaucus, Leber). The cornea turns yellow and the disease is accompanied by pus in the anterior chamber. Necrosis of the cornea is also a rare complication of *facial erysipelas*. After experimental division or *destructive disease* of the *fifth nerve*, corneal necrosis is common, unless the lids are kept closed. It is not yet definitely known whether this accident results only from trauma and desiccation of the exposed and anæsthetic cornea, or whether the trigeminus exerts an influence on its nutrition.

9. A neurosis of the cornea, characterized by intense pain and photophobia, but with scarcely any injection of the pericorneal vessels, is sometimes seen weeks or months after minute injuries to the cornea. Careful inspection shows that it is due to an inflammatory condition of the minute cicatrix left by the injury.

VI. Iris.

1. Unequal intensity of color of the iris of the two eyes has been found by Féré[17] sixty-two times in the examination of seventy-six cases of *hysteria*, and is considered by him as a characteristic hysterical stigma. Discoloration of an iris (especially a blue iris) may, however, remain as well after iritis. The existence of a past iritis is revealed by deposits on the anterior capsule of the lens, which are rarely absent when the dilated pupil is examined (unless the iritis was treated early and thoroughly by atropia).

2. Plastic iritis may depend on various well-known causes. A localized inflammation of the iris results from the pressure of a swelling lens undergoing cataractous change, even where no infection exists. Severe contusion of the eyeball is often followed by iritis, probably due to secondary infection. Ulcers of the cornea frequently lead to the same result, and iritic complication is not rare in parenchymatous keratitis, whatever be its cause. The most frequent cause of non-traumatic iritis is *syphilis*. Syphilitic iritis is an early manifestation, and usually bilateral. In the later stages of syphilis a (one-sided) iritis is sometimes seen with *gummatous* tumors in the iris. It must not be overlooked that in a person who has once acquired syphilis, iritis may also occur from other causes, in which case anti-syphilitic treatment has no influence upon it. Another known cause of iritis is *rheumatism*. While the origin is often suggested by the patient's previous or present rheumatic history, it can be but rarely proven by any specific influence of recognized anti-rheumatic remedies. Very often the name "rheumatic" iritis hides our ignorance of its causation. Iritis may also accompany *gonorrhœal rheumatism*, and is indeed sometimes observed as the only manifestation of this disease. Whether *gout* can provoke iritis is still a matter of doubt. Similar doubts exist as to the origin of iritis from *kidney disease*. *Diabetes* leads occasionally to a rebellious iritis, which improves when the systemic condition is controlled. *Influenza* has been followed rather frequently by iritis during the recent epidemics. In *leucocythæmia* characteristic infiltration with diffuse inflammation has been observed in the iris. Tumors in the iris, with subsequent diffuse iritis, can be referred etiologically either to this disease, viz., *leucocythæmia* (rare), to *tuberculosis*, or most commonly to *syphilis* (gummata).

A cause of iritis which has as yet received but insufficient attention is *nasal suppuration*. Ziem has pointed out the possible connection between rebellious iritis and *suppuration* of the *accessory sinuses* (especially the maxillary antrum). The writer's experience has also included cases of recurrent iritis which were regularly preceded by acute coryza.

Iritis is usually one of the manifestations of sympathetic ophthalmia, the inflammation of an eye due to chronic inflammation of the ciliary region of the other eye, generally dependent on the presence of a foreign body. Such iritis is, however, associated with inflammation of the ciliary body, and often also of the deeper parts of the eye.

Unlike the plastic form of inflammation, serous iritis is a local disease of which we know no etiological connection with other disturbances.

VII. Pupil.

1. The pupil is smaller during the first few weeks of life, and also during the senile period, than during youth and middle age. It is also narrower in hypermetropia than in the short-sighted eye under the same illumination. The absolute width varies inversely with the intensity of the light.

2. The pupil is contracted in iritis as well as in severe inflammation of the cornea or conjunctiva, or even in intense irritation by the presence of foreign bodies. It is characteristically wide and immobile in glaucoma, even if attended by inflammatory symptoms. It enlarges in all diseases of the eye or optic nerve in which the sensibility to light (not merely the distinctness to sight) is reduced, and attains a medium width in one-sided absolute blindness. If the pupil is normal in size and reaction in an eye said to be blind, the condition is either hysteria or simulation. The pupil is still wider in bilateral blindness, as the perception of light by one eye influences the pupil of the other. The pupil of a blind eye, therefore, still responds to the illumination of the other (sensitive) eye. If in double-sided blindness the pupils react to light, the lesion must be situated in the brain above the pupillary centre in the corpora quadrigemina, *i.e.*, in the cortex or white substance of the occipital lobes. Such instances have been observed after cerebro-spinal meningitis.

3. A wide and absolutely immobile (*i.e.*, not sensitive to illumination) pupil indicates paralysis of the motor oculi nerve, be it by the effect of drugs on its termination, by disease of the trunk, or of the central origin of the nerve. The pupil, if wide from inactivity of the third nerve, is enlarged still further by the local effect of atropin.

Dilatation of the pupil is also caused by activity of the cervical sympathetic nerve, either experimentally or as the result of irritating lesions in acute disease of its origin in the cervical spinal cord. Under these circumstances the reaction to light is not impaired. The influence of the sympathetic upon the pupil is also manifested in a reflex manner whenever painful impressions are made upon the skin. This dilatation, very slight ordinarily, is more easily observed in so-called "nervous" subjects, but particularly during incomplete ether or chloroform narcosis. Indeed, during surgical anæsthesia the pupil is an index of the sensibility.

Contraction of the pupil indicates activity of the third nerve or paralysis of the sympathetic. In paralysis of the cervical sympathetic in man, from disease or injuries, the resulting contraction is only moderate and not always permanent.

4. The pupil is contracted during natural sleep and during narcosis, but dilates whenever pain is felt and whenever asphyxia occurs. The narrowness of the pupil during *opium stupor* serves to distinguish this condition from *coma*, in which the pupil is wide.

5. Pupillary disturbances are very common in diseases of the nervous system, but they are generally not charac-

teristic symptoms. In *meningitis* narrowness is usually seen, while dilatation in this disease indicates brain pressure from effusion or hemorrhage. All localized destructive lesions in the brain dilate the pupil when they involve the nucleus or the trunk of the third nerve—for instance, *syphilitic meningitis, apoplexy,* and *embolic* infarctions. In *general paresis* pupillary symptoms have been found in one-third to two-thirds of all cases. They consist rather in equality of the two pupils than in marked dilatation or contraction in either eye. In fact, inequality of the two pupils, if not explicable by an intra-ocular or peripheral nerve lesion, may be considered a grave symptom, even during apparent health, indicative of cerebral changes. It is a very common precursor of various forms of insanity.

6. Pupillary inequality occurs in at least one-third of *tabetic* patients, usually early. Less common in this disease is the "Argyll-Robertson pupil"—a marked contraction without reaction to light, but with slight increase in the contraction during efforts at accommodation (usually bilateral). The same form of pupil occurs also in other forms of disease of the cervical spinal cord. In Pott's disease of the cervical region the pupil is occasionally disturbed, sometimes dilated, more often contracted. *Epileptics* often show a permanently wide pupil. The same may result (by reflex stimulation of the sympathetic ?) from pelvic or intestinal irritation (worms). Various transient pupillary changes are not uncommon in *hysteria.*

Enlarged glands, tumors, and aneurisms pressing upon the *cervical sympathetic* nerve cause pupillary contraction.

7. Pupillary dilatation and immobility, with paralysis of the accommodation, is a characteristic symptom of *ptomaïne poisoning* from tainted meats, sausages, or fish. The same paralysis of the third nerve occurs in *belladonna* poisoning. Whenever this condition comes on suddenly, either in one eye or in both, without other nervous symptoms, the first suspicion should be that of local *atropin* or *belladonna* action.

VIII. Accommodation.

1. Enfeeblement of the accommodation reveals itself by inability to read or to see distinctly at a proximity at which the patient could formerly see distinctly. As the accommodative power diminishes normally from youth until about the fifty-fifth to sixtieth year, when it is practically lost, the age of the patient must be taken into account in all consideration of the faculty of adjustment. Likewise the refraction of the eye must be known before the accommodation can be measured. Of intra-ocular conditions the prodromal stage of glaucoma manifests itself by rapid diminution of accommodation.

2. The accommodative power is further reduced in many conditions which derange nutrition or lower the general vigor, as neurasthenia, kidney disease, diabetes, derangements of the liver, after hemorrhages, and during recovery from exhausting fevers. More characteristic is the influence of carious teeth, in consequence of which Schmidt[18] saw the accommodation enfeebled 73 times in 92 instances, and sometimes only on the side of the defective teeth. This observation does not seem to have been confirmed by others.

3. Absolute paralysis of the accommodation without pupillary change follows diphtheria very frequently in the course of two to four weeks. It is indeed characteristic of the after-effect of the diphtheritic poison. Whether the same paralysis can follow scarlatina and mumps, or whether an error had not been committed in the diagnosis of these affections in the instances observed is an open question, with greater probability of the latter view. An incomplete paralysis of the accommodation, with either normal or contracted pupils, may be a hysterical symptom, but occurs also in ataxia.

4. When accommodation and sphincter of the iris are paralyzed together, the cause may be local or general belladonna influence, ptomaïne poisoning, or lesions of the third nerve, particularly cerebral syphilis, less commonly ataxia.

5. Spasm of the accommodation is a term often misapplied in ophthalmic literature. The correction of farsightedness by involuntary contraction of the ciliary muscle is not a spasm properly speaking, as it serves a useful purpose and is not maintained when the eyes are not used in the dark. It is distinguishable from true spasm by relaxing under ophthalmoscopic examination. True spasm simulating myopia is not common. It occurs perhaps more often in low degrees of astigmatism than in any other condition, and is brought on by overuse of the eyes and a neurotic disposition. The writer has once seen it accompany hemiplegia from brain lesion.

IX. Asthenopia.

1. The inability to use the eyes persistently, on account of indistinctness of sight or discomfort and pain, headache, and other nervous symptoms induced by steady application, is so common a complaint, and due to so many different influences, that it deserves special mention in an article of the present scope. While the most important cause of asthenopia are optic defects, viz., hypermetropia, astigmatism, or insufficiency of the accommodative power, we cannot ignore accessory influences due to conditions of the general system even in connection with ametropia. Besides asthenopia may occur in optically perfect eyes. According to the writer's experience in private practice about twenty-five per cent. of the patients with asthenopic complaints do not belong to the class which can be relieved by glasses.

2. The cardinal symptoms which indicate anomalies of refraction (H. or As.) or insufficient accommodation (presbyopia) are either blur on persistent eye-use or discomfort, described as fatigue and ache (much less commonly as a burning or shooting pain) or both. But in patients with any neurotic disposition—and this comprises a large class of civilized communities — these annoyances are apt to be complicated by headaches, feeling of pressure in the head, and, more rarely, vertigo, or even nausea. While such accessory neuroses can be checked just as promptly as the asthenopic symptoms proper by means of suitable glasses, and their dependence on eye strain be thus proven, a critical experience shows that they occur only in individuals whose antecedents or family history indicate a neurotic disposition, or who have been subjected to damaging influences, as continued overwork with confinement, anæmia, or diseases deranging nutrition, like intestinal disturbances, or who are the victims of neurasthenia. Indeed, by removing such injurious factors, if possible, the neuroses can sometimes be relieved without attention to the eyes, although the eye strain persists. It can be further observed that the degree of ametropia which can exist in different persons without asthenopic complaints varies with the health and muscular vigor. While delicate individuals may at times be sensitive to half a dioptry of astigmatism, or three-fourths dioptry of hypermetropia, persons in perfect health do not necessarily suffer from two dioptries of ametropia until age reduces their accommodation, or weakening influences of any kind enfeeble their power of endurance.

3. Other ocular conditions which may cause asthenopia are blepharitis and chronic conjunctivitis (especially when due to lachrymal obstruction), the intra-ocular irritation due to myopia (not the mere optic condition of M.), and slight choroiditis, perhaps not yet sufficient to damage sight. These causes are more apt to produce burning and smarting eyes, sometimes with blur, on using the eyes, as contrasted with the predominance of aching from accommodative or refractive anomalies.

To what extent anomalous tension of the external muscles of the eyes is responsible for asthenopic symptoms is at present a subject of much discussion. That a certain class of authors have enormously exaggerated the importance of so-called "heterophoria," or want of balance of the recti muscles, cannot but be patent to any unbiased observer in practice. On the other hand, cases do certainly occur, even if they are not common, in which asthenopia and discomfort are associated with tendency to

strabismic deviation of the eyes whenever binocular vision is obviated. But whether these two conditions bear a causal relation to each other, or whether both are indicative of neurasthenia, requires further study.

4. Of extra-ocular causes of asthenopia nasal anomalies—stenosis or suppurative processes—are the most important. Nasal influence manifests itself, however, more frequently in the form of itching and burning of the lids (especially in the morning), and irregular, dull, or shooting pains than in the form of typical asthenopic symptoms, although the latter, too, are sometimes referable to a nasal origin. A variety of influences—anæmia, recovery from exhausting diseases, stomach troubles, defective teeth—may cause asthenopia indirectly by enfeebling the accommodation, but such cases may be termed of accommodative origin, and can be benefited by glasses. In other instances, however, neurasthenia proper, or the nervous breakdown from disturbed digestion, leads to inability to maintain the use of the eyes without increasing discomfort, which no glasses can benefit. Foerster[19] has described, under the name kopiopia hysterica, a variety of incurable asthenopia, dependent on chronic sclerosing parametritis. No confirmation of his observations have as yet been recorded by others.

X. Lens.

1. Opacity of the lens, cataract, occurs whenever any extensive rent is made in the lenticular capsule by any traumatism. It may result also from severe concussion of the eyeball, without perforating wound, following the injury in such cases in the course of weeks or months. Of intra-ocular conditions which may lead to cataract may be mentioned recurrent attacks of iritis, chronic cyclitis, chronic or absolute glaucoma, chronic choroiditis, and retinal detachment, as well as high degrees of progressive myopia. Senile cataract is very common in advanced age, even in perfect health and with ideal eyes, especially if we examine the extreme periphery of the lens. Fortunately not every instance of peripheral senile cataract proceeds to opacity of the pupillary area.

2. The most common condition leading to premature senile cataract is *diabetes mellitus*. Whether *kidney disease* has the same influence, as Deutschman has asserted, is not yet definitely decided. Hogg[20] has called attention to the frequent association of *prostatic enlargement* and *stricture of the urethra* with senile cataract.

3. Zonular, or lamellar cataract, commonly congenital and not rarely a family anomaly, has been referred by Horner and his disciples to the influence of *rickets* (sometimes ante-natal). While the coincidence of the two affections has been shown to exist in about forty per cent. of the cases, no such relationship can be proven in other instances.

4. Cataract has been known to come on rapidly in persons struck by *lightning*.

Diffuse cataract can be produced in animals by *naphthalin poisoning*.

XI. Choroid and Vitreous Body.

1. Choroidal changes occur frequently in high degrees of myopia. The least dangerous lesion is pigmentary absorption, permitting a view of the choroidal vessels. More serious is hypertrophy of the pigment in the form of irregular masses. The gravest form is constituted by central white plaques (of inflammatory or atrophic origin ?) which damage central vision. Hemorrhages into the retina and vitreous body, evidently from choroidal vessels, are another familiar accident in strongly myopic eyes.

2. In the more common forms of choroiditis, characterized by yellowish plaques of infiltration, generally with pigmented border and later on by white atrophic spots with diffuse pigment proliferation, and not due to myopia, no cause can, as a rule, be ascertained, except it be *syphilis*. But the statements as to the frequency of syphilitic choroiditis vary very much. Extreme opinions are, perhaps, represented by Hutchinson[21] and by Alexander.[22] While the former maintains that syphilis should be suspected in every case and its existence tested by mercury, although he admits that it is not the only cause of choroiditis, Alexander—from an exceptionally large experience—believes that syphilis is not responsible for areolar or disseminate choroiditis, except when associated with opacities of the vitreous body. The same observer, in harmony with general experience, describes as syphilitic the following forms, viz.: *a*, irido-choroiditis with vitreous opacities; *b*, vitreous opacities without visible choroidal change, except, perhaps, atrophic patches in the most anterior region; *c*, gummata in the choroid; *d*, diffuse chorio-retinitis, especially in the peripheral parts of the ocular tunics, simulating retinitis pigmentosa (the same form may occur in hereditary syphilis); and *e*, many of the cases of the ordinary areolar or disseminate choroiditis, if attended with vitreous opacities, and especially so, if they become complicated with a central exudative chorio-retinitis, characterized by the sudden appearance of a white plaque near the macula with opacity of the vitreous and deposits on the posterious surface of the cornea, as described by Bergmeister. Yet the present writer has seen three cases which correspond exactly to Bergmeister's description, except that they were not preceded by previous choroiditis and pursued a less malignant course, but which occurred in patients *free* from syphilis.

3. In the course of *cerebro-spinal meningitis* a purulent choroiditis (sometimes irido-choroiditis), and always (?) binocular, characterized by a yellow reflex on illuminating the pupil, is not uncommon. It necessarily leads to atrophy of the eyeball. Browne[23] has described another variety of choroiditis, in the form of a few central whitish foci, either reabsorbed later on or leading to circumscribed atrophy, as characteristic of a transient *meningitis* in children. A suppurative choroiditis due to septic embolism and leading rapidly to suppurative ophthalmitis, generally one-sided, but sometimes even affecting both eyes, is an occasional accident in *pyæmia*, particularly, but not exclusively, of *puerperal* origin. *Relapsing fever* is often followed by various forms of choroiditis, particularly a serous irido-choroiditis, with opacities in the vitreous body (Logetschnikow). *Malarial* poisoning also may affect the uveal tract, manifesting itself in some instances by vitreous opacities even with hemorrhages, in others by a diffuse chorio-retinitis.

4. Opacities in the vitreous body occur in many of the more acute forms of choroiditis. They may be formed, however, without ophthalmoscopically visible (or easily overlooked) changes in the choroidea, from traumatism by perforating or blunt force, in myopic eyes or in the course of syphilis and malaria. In many instances no local or constitutional cause can be detected.

5. Hemorrhages occur in the vitreous body from trauma, violent exertions (probably only in the case of sclerotic or other vascular disease), in progressive myopia, in malaria, purpura, and in high degrees of anæmia, and in hypertrophy of the left ventricle of the heart.

6. The vitreous may be the seat of a free cysticereus vesicle, the embryo of which has entered the eye through the blood-vessels in consequence of eating measly pork (more rarely from auto-infection from an intestinal tænia).

7. In extensive miliary tuberculosis—and less frequently in tubercular meningitis—tubercles may be seen in the choroid by means of the ophthalmoscope, in the form of multiple yellowish raised exudations in the choroidal tissue underneath the normal retina, of a size less than that of the optic disk. Single larger tubercular tumors in the choroid are less common. Of course, tuberculosis leads soon to further inflammatory charges and opacity of the media.

XII. Retina.

1. Of all intra-ocular lesions, the affections of the retina and of the optic nerve are of the greatest interest to the general practitioner on account of their frequent dependence on nervous or constitutional lesions which are not rarely revealed by this localization earlier than by any other symptoms.

In the normal eye ophthalmoscopic examination does not show any pulsation of the retinal arteries, but very often a slight pulsating movement is seen in the larger portions of the retinal veins as they are traced in their course across the bright optic disk. The systolic dilatation of the arteries is evidently too slight to be seen ordinarily in vessels of such small calibre. But the increased intra-ocular tension caused by the systolic influx of blood suffices to compress visibly the more yielding veins. Where the intra-ocular tension is low, or where the sclera is freely distensible the venous pulsation is not visible. On compressing the eyeball with the finger, the pulsation of the veins becomes more distinct, and with increasing pressure the arteries also begin to pulsate visibly. When the intra-ocular tension is increased by glaucoma the arterial pulsation is likewise manifest.

2. Pulsation of the retinal arteries without increased tension of the eyeball or other ocular symptoms is often found in *insufficiency* of *the aortic valves*, much less frequently in other *cardiac* or *valvular* anomalies. It has also been seen in rare instances of extreme *anæmia* (and sometimes in acute fever, pneumonia, and phthisis). Very feeble arterial pulsation has been observed in one eye in aneurism of the arch of the aorta, or of the large arteries of the neck on the corresponding side of the body.

Dilatation of the retinal arteries up to the normal calibre of the veins was observed by Becker in *exophthalmic goitre* (four times in six cases). Of extreme dilatation of all retinal vessels, Knapp records a case in connection with general dilatation of the vascular system. Venous congestion due to compression of the jugular veins, by goitre and other tumors, or to pressure of any kind upon the venæ cavæ, may reveal itself, too, in the veins of the retina. In a case of venous congestion due to cardiac malformation, Liebreich found the retinal veins distended and of a cyanotic appearance.

3. Miliary aneurism of the retinal arteries coexistent with miliary aneurism of cerebral arteries (the most frequent cause of apoplexy) have been found at autopsies, but have but rarely been seen ophthalmoscopically.

4. Sclerosis of the walls of the arterial system extends into the retinal vessels in about one-half of all cases (Raehlman [24]). It reveals itself by tortuosity of the vessels, and thickening and opacity of their walls, so that the (normally invisible) walls are indicated by a marked double contour. There are irregular contractions in the calibre of the vessels, so that the column of blood may appear spindle-shaped in some of the branches. As long as hemorrhages have not occurred vision is not disturbed.

Changes similar to those produced by arterio-sclerosis have been observed in the retinal arteries in advanced syphilis. Indeed, in this disease the thickening of the wall may proceed to obliteration of the calibre of an arterial branch. Fuerstner and Haab have shown that this obliterating syphilitic endarteritis co-exists in the retinal and cerebral arteries, and that the ophthalmoscope may hence facilitate the diagnosis of cerebral syphilis. Frequently the changes in the syphilitic retinal vessels, however, are accompanied by syphilitic retinitis.

5. Very characteristic changes are found ophthalmoscopically in embolism of the central artery. With immediate blindness the retinal arteries are found nearly empty (at least at first), the veins distended, and turbidity around the edges of the disk, with a cherry-red spot in the centre of the macula. The embolus is derived from some lesion in the heart or arterial system, but in some instances no source can be found. Kern [25] has recently shown that the diagnosis of embolism in the alleged cases is often wrong, and that the lesion may be a thrombus in an atheromatous artery. Sometimes only a single retinal branch is obliterated. A few times the permanent blindness was preceded by short transient spells of blindness, perhaps due to temporary occlusion by an embolus too small to arrest the circulation completely, but increasing in size by gradual coagulation in the vessel.

Remarkable narrowness of the arteries has been observed in a few instances of sudden blindness in persons with enfeebled circulation, but in whom no embolus existed in the vessels (Alf. Graefe and Knapp). While the pathology of this "ischæmia retinæ," as it was termed, is not clear, the influence of the retinal anæmia upon the sight was proven by the relief on lowering the intra-ocular tension (by paracentesis or iridectomy).

6. Retinal hemorrhage may occur in the course of most forms of retinitis or severe inflammation of the optic nerve. They are very profuse and multiple in thrombosis of the central vein of the retina, a condition manifesting itself by intense congestion and tortuosity of all the veins, with hemorrhages along the vessels and inflammatory cloudiness of the papilla.* Thrombosis of the vena centralis is sometimes referable to general ill-nutrition (marasmus), sometimes to pulmonary *emphysema*—oftener to disease of *the heart* or *arteries*. It has also been observed after extensive burns of the skin, and after facial erysipelas. Emphysema of the lungs, if complicated with hypertrophy of the left ventricle, is also apt to cause retinal hemorrhages without thrombosis. Hemorrhages into the retina are observed as well in *pernicious anæmia*, and even in ordinary severe *anæmia* from loss of blood in *kidney disease*, in *diabetes*, in *gout* (?), in disease of the liver with jaundice, after trauma of the eye, after violent exertions or coughing-spells, and after death by asphyxia. If produced in apparent health, without trauma to account for them, they indicate vascular disease, *arterio-sclerosis, fatty degeneration*, or *syphilitic endarteritis*, and serve as a warning of threatening cerebral apoplexy. There has been observed, however, a rare form of extensive hemorrhage in young people (of fifteen to twenty-five years) in apparently perfect health, in whom it has no such grave general significance.

The disturbance of sight produced by hemorrhages depends on their size, extent, and location.

7. Inflammations of the retina present so many different characteristics that the ophthalmoscopic observer can recognize their cause in the more typical forms with certainty and even in the less pronounced instances with some probability. The most common form, viz., the retinitis albuminurica complicating *kidney disease*—always bilateral—consists in its simplest form in turbidity of the edges of the disk, fatty-looking white patches, often with brownish border, in the retina, at first near the papilla and later on all over the fundus, dilatation of the veins, and hemorrhages partly along the vessels, partly in the form of small spots around the centre of the retina. Later on, a characteristic star-figure, made up of small white dots around the macula, is common. The walls of the vessels often appear as visible white contours. But deviations from this type also occur. The disease is sometimes limited to a narrow zone around the papilla, and still more rarely consists only in inflammation of the optic disk with hemorrhages.

Albuminuric retinitis, especially in the last-mentioned forms, may be simulated (rarely) by optic neuritis of cerebral origin. In its less pronounced type it resembles the retinitis caused by diabetes. In most instances, however, the ophthalmoscopic examination can recognize kidney disease when manifested by retinal lesions.

Retinitis occurs in at least seven per cent. of all cases of renal affection. It is most common in interstitial nephritis, less so in parenchymatous kidney disease, and rare in amyloid kidney. In nephritis following scarlet fever and the kidney trouble of pregnancy the retinal lesions are not considered of prognostic significance and may disappear without injury to sight as the causative affection heals. But in Bright's disease, not coming under this etiological category, it is a sign of great importance. Miley [26] examined 164 cases of Bright's disease with regard to the significance of the albuminuric retinitis. Of 51 patients who had retinitis, 27 died inside of two years; while of 105 whose eyes were normal only 28 succumbed within the same time (8 patients

* It is not yet certain whether these appearances are necessarily due to thrombosis or whether there exists a hemorrhagic or apoplectic retinitis without thrombosis.

had other ocular lesions independent of their disease). According to microscopic researches by the Duke Charles Theodore (of Bavaria) the retinal lesions are the result of hyaline degeneration and obliterating endarteritis of the retinal vessels.

8. *Diabetic* retinitis in its most typical form consists of small white spots irregularly scattered throughout the centre of the retina, not arranged in star-figure, without colored border, and without involvement of the optic disk. The disease is bilateral, but often more advanced in one eye. If the ophthalmoscope shows in diabetes retinal lesions like those of Bright's disease, albumin will also be found in the urine. In other cases of diabetes mellitus there occurs no typical retinitis, but simply hemorrhages followed by irregular patches of white retinal degeneration. Many such eyes become affected with glaucoma.

9. Diffuse, but more or less striated retinal opacity with copious hemorrhages along the dilated vessels, especially near the retinal centre, is seen occasionally in *leucocythæmia*, while a similar form of retinitis, but, it is said, with more diffuse multiple but small hemorrhagic spots, is more characteristic of *pernicious anæmia*.

10. *Syphilis* may affect the retina in various ways. The typical simple retinitis of syphilitic origin described by Jacobson appears as slight cloudiness of the papilla and retina with venous dilatation and, usually, fine vitreous opacities, but without plaques or hemorrhages, and generally with but moderate interference of sight. It is an early form, usually occurring inside of two years after infection, and being protracted only if not treated. In other instances more marked opaque striæ accompany the vessels as they emerge from the papilla. Ole Bull considers a very faint peripapillary opacity and vitreous turbidity as quite common in the first period after infection, and claims that it is characterized by an irregularly ring-shaped relative scotoma, which surrounds the point of fixation but includes the blind-spot (optic disk), but he states that the scotoma can only be detected with gray, not with white objects.

Hirschberg,[27] on the other hand, states that there occurs, commonly within the first two years of syphilitic infection, a form of retinitis, or perhaps syphilitic panophthalmitis, which is not rarely overlooked, as it need not reduce sight much, but may annoy the patient by flickering. It is accompanied often by fine deposits on the posterior surface of the cornea, and usually by fine vitreous dust, while in the retina there can be seen, on close examination, faint pinkish-yellow, later on, whitish spots, adjoining some of the smaller vessels in a manner comparable to berries on a stem. The form of retinitis characterized by Von Graefe as a late manifestation of syphilis and termed by him central relapsing retinitis, as it appears in the form of a central grayish retinal cloudiness which relapses even under specific treatment, does not seem to have been often observed. Late syphilis also manifests itself by obliterating endarteritis in the retina, sometimes with hemorrhages. The retina is likewise involved, as seen by its turbidity and the invasion of its anterior layers by pigment in the diffuse chorio-retinitis observed both in tertiary and in hereditary syphilis (the disease beginning peripherally in the latter case and resembling retinitis pigmentosa).

11. In *gout* Hirschberg[28] has described a retinitis characterized by white dots in the deeper layers and arranged in lines partly radiating from the macula and partly crossing these so as to form a network, together with small hemorrhages. Hutchinson considers a diffuse retinitis with hemorrhages suggestive of gout. Retinal hemorrhages with sclerosis in the form of opaque striæ have been observed a few times in connection with marked oxaluria.

12. A *septic* retinitis, in the form of white plaques, which speedily develops into panophthalmitis, is a dangerous accident due to embolism from some pyæmic source in *puerperal fever*, extensive *phlegmons*, malignant *endocarditis*, or surgical pyæmia.

Retinitis of traumatic origin, macular injury by intense solar illumination and by lightning, extension of inflammation of the optic nerve into the retina, and participation of the retina in choroiditis, complete the list of retinal inflammations the etiology of which is more or less understood. There remain comparatively rare instances of inflammatory retinal affections—diffuse retinitis with turbidity of the entire membrane, central transient retinitis causing a circumscribed scotoma, retinitis punctata albescens, retinitis proliferans with connective (?) tissue striæ—the origin of which are not known.

An inexperienced observer may mistake patches of opaque (myelated) nerve-fibres which sometimes radiate from the papilla in normal eyes, for retinitis or neuroretinitis, but the normal vessels and the absence of all diffuse turbidity, as well as the location of the opaque spots, should guard against this error.

13. The only etiological data we possess regarding the origin of pigmentary retinal degeneration (retinitis pigmentosa) refer to consanguinity on the part of the parents of the victims in one-fourth to one-third of the cases, the occasional occurrence of the disease in several members of a family, as well as the comparative frequency of other degenerative conditions, like deaf-mutism, in such families.

XIII. Optic Nerve.

1. The vascularity of the optic nerve varies within such wide physiological limits that the diagnosis of either papillary congestion or, on the other hand, of anæmia, must be received with caution. An intensely congested optic disk means really neuritis, while pathological pallor has only been observed in the last stages of cholera, in grave anæmia, and in quinine amaurosis.

2. It is best to describe the inflammation of the intra-ocular end of the optic nerve as papillitis, since inflammation of the trunk of the nerve back of the eyeball (retro-bulbar neuritis) is not necessarily visible ophthalmoscopically. Whenever the ophthalmoscope shows swelling and turbidity of the optic disk, indistinctness of its edges by reason of cloudiness, and dilatation of the veins (often with hemorrhages), we speak of papillitis, and if the cloudiness extends into the retina, of papillo-retinitis, while optic neuritis refers to inflammation of the nerve, no matter whether it extends down to the visible end of the nerve or not.

Papillitis of intra-ocular origin accompanies retinitis, especially the albuminuric form; the more violent forms of early syphilitic retinitis, also—sometimes—exudative choroiditis and acute forms of chorio-retinitis. Sympathetic ophthalmitis may also begin in the form of neuritis.

3. Of extra-ocular causes facial erysipelas may lead to optic neuritis. One-sided papillitis—which is otherwise much less frequent than the bilateral affection—may be due to orbital disease, phlegmon of the orbit, inflammation of the sheath of Tenon, caries (tubercular or syphilitic) of the orbital walls or—least of all, numerically—orbital tumors. Suppuration of the antrum of Highmore or of the frontal sinus has also been found as a rare cause of optic neuritis.

4. Papillitis of one or both eyes is sometimes, but not often, due to (late) *syphilis* of the optic nerve. More frequently, if syphilis is the cause, the neuritis is secondary to its cerebral localization. Neuritis, usually bilateral and of grave danger to vision, although the visible papillary inflammation is generally very slight, has been observed after severe *hemorrhages*—especially hemorrhages from the *stomach*,—after *measles*, *typhus* and *typhoid* fever, *mumps*, and particularly often after *influenza*. In other instances rheumatism, suppression of menstruation and of bleeding from hemorrhoids, "taking cold," have been accused as causes of optic neuritis, but without definite proof.

5. Papillitis may also result from poisoning by bisulphide of carbon, or more frequently from lead-poisoning. In most instances, however, poisons affecting the optic nerve cause retrobulbar neuritis, which can but exceptionally be recognized ophthalmoscopically and which will hence be referred to under the head amaurosis (XIV., 6).

6. Of chief interest to the clinicist is the relation of optic neuritis to diseases of the brain. Von Graefe made a distinction originally between ordinary optic neuritis of cerebral origin, which he called the descending neuritis, and the condition termed by him choked disk (Stauungspapille). While in the former case the autopsy shows a uniform inflammation of the nerves from the chiasm to the eye, choked disk may exist with but little evidence (to the naked eye) of neuritis of the nerve-trunk, but with intense swelling and venous stasis of the intra-ocular end. Accordingly von Graefe assumed a creeping down of the inflammation along the nerve in the former case, while he attributed the choked disk to interference with the return of venous blood by increased intracranial pressure. He based this explanation on the fact that choked disk commonly accompanies conditions which raise the intracranial pressure like tumors. But it was soon shown that this mechanical view was untenable on account of the free anastomoses of the veins of the orbit with the facial vein. Subsequently Schmidt, and, later on, Manz, tried to prove that the venous interference was an indirect one, due to dropsical exudation between the sheaths of the optic nerve, which transmitted the intracranial pressure to the central vein after it enters the optic nerve. That this intervaginal dilatation does exist in such cases has been shown by autopsies. But its significance has been overthrown by Deutschman.[29] His experiments showed that any degree of compression of the nerve by intravaginal fluid comparable to what exists in pathological cases, is insufficient to produce optic neuritis. Its real pathogenesis he seeks in the influence of germs or toxines carried down the intravaginal space from the brain by the current of fluid, and he therefore considers the papillitis as a transmitted infection. While the distinction between ordinary optic neuritis and choked disk can be maintained ophthalmoscopically in extreme cases of either type, average experience shows that the two conditions really merge into each other.

The cerebral disease which most commonly leads to papillitis is *tumor* of the brain. The association of the two conditions is so frequent that in doubtful cases the diagnosis of cerebral tumor is materially confirmed by the presence of optic neuritis. According to Reich[30] neuritis (or the atrophy resulting from it later on) was found in 95.4 per cent. of eighty-eight cases of tumors examined during life and after death. In the analysis of ninety-six reported cases, Edmonds and Lawford[31] found neuritis in eighty-six per cent. of all tumors of the cerebellum, the cerebral ganglia, or the base of the brain, but only in forty-six per cent. of the tumors seated in the cerebral cortex. Hughlings Jackson, on the basis of a large personal experience, thinks that optic neuritis would ultimately set in in every case of tumor were it not for the premature death of some patients. For sometimes the neuritis is a late accident. Occasionally it disappears without leaving any lesion, sometimes to relapse again. Oftener it changes into atrophy of the nerve. In spite of the intense swelling of the papilla vision is but little reduced in some patients. The affection is almost invariably binocular.

Inflammation of the optic nerve, but often with less intense papillary venous congestion than in the choked disk of brain tumors, occurs also in other cerebral affections, but is not nearly so common as in tumors. It has been observed in instances of *pachymeningitis*, of *meningitis*, tubercular, syphilitic, and otherwise, but only very rarely in the *cerebro-spinal* form. It is not uncommon in *abscess* of the brain, especially abscesses of the temporal lobes from ear disease, and in such cases it is unilateral on the side of the abscess. It has also been seen in *hydrocephalus internus* and in thrombosis of the cavernous sinus. In cerebral *embolism* and softening and in *apoplexy* it is very uncommon, except when the effused blood gets in between the membranes at the base. In *diffuse sclerosis*, the *non-inflammatory* forms of *insanity*, and *degenerations* in the brain, optic neuritis is a very exceptional occurrence. A few times optic neuritis has been seen in connection with acute myelitis of the spinal cord. The disease has also been known to follow sunstroke.

7. Atrophy of the optic nerve shows itself by white discoloration of the papilla, often with a greenish-blue or grayish tint, and by failure of sight. If of intra-ocular origin or secondary to optic neuritis the vessels of the atrophied optic nerve are generally contracted. But if the atrophy is due to other causes the vessels may retain their normal calibre.

Atrophy may follow any papillitis which does not speedily cease. It may also result from intra-ocular disease in which the optic disk was not primarily inflamed, such as embolism of the central artery, persistent forms of retinitis (retinal pigmentary degeneration), choroiditis, and chorio-retinitis, and especially glaucoma. It may be the consequence of previous optic neuritis, due to any of the causes mentioned in the former paragraph, as facial erysipelas, lead-poisoning, orbital disease, syphilis, and the various brain troubles engendering inflammation of the optic nerves. With but little intra-ocular manifestation an optic neuritis, involving principally the trunk behind the eye, may follow *loss of blood*, especially from the *stomach*, measles, *typhus* or typhoid fever, mumps and influenza and lead to atrophy. Retrobulbar neuritis due to *tobacco* and *alcohol* poisoning rarely leads to extensive atrophy, but the inflammation of the nerve caused by diabetes may terminate in complete degeneration.

8. Atrophy may occur without previous neuritis by compression of the nerve from traumatic hemorrhages into the orbit or fracture of the walls of the optic canal, from exudation into the orbit or tumors of its walls, from irregular growth of the sphenoid bone (as in acromegaly) or exostoses on its upper surface, from suppurative inflammation of the sphenoid sinus, from anomalously situated or arterio-sclerotic vessels of the circle of Willis, constricting the nerve, or from aneurisms or tumors of any kind pressing upon it. If the compression occurs between the chiasm and the eye the atrophy becomes visible ophthalmoscopically in the course of weeks, while if the function of the optic tracts posterior to the chiasm be destroyed it will require many months or years before the atrophy descends to the intra-ocular end of the nerve. If the cause of the paralysis of the nerve is situated between the basal ganglia and the cortex of the occipital lobes, the atrophic changes may not reach the eye at all in adult life, although during infancy the degeneration pursues a more rapid course. The cerebral affections which may cause atrophy by compression of the region of the chiasm, are distention of the third ventricle by *internal hydrocephalus* and *basilar meningitis* (besides tumors of the bones of the base of the skull). Foci of softening and apoplectic effusion lead but rarely to atrophy by compression. Whenever the inducing cause is at the periphery of the brain, away from the chiasm, the affection is unilateral, but bilateral if the lesion is situated at or near the chiasm.

9. Atrophy not traceable to compression of the nerve is frequent in *multiple sclerosis* of the brain and in *general paresis;* somewhat less common in other forms of mental disease dependent upon degenerative changes. In these instances it is always bilateral, but often unequally advanced in the two eyes, and does not necessarily proceed to complete optic paralysis. Blindness from atrophy is an occasional incident in the course of polio-encephalitis inferior—or in the progressive sclerosis of the nuclei of the upper cranial nerves.

10. Atrophy of the optic nerve is often of spinal origin. In *locomotor ataxia* optic atrophy has been counted in from twelve to twenty-six per cent. of all cases by different observers. It may be one of the earliest symptoms. Its prognosis, if of spinal origin, is always bad, although a temporary standstill for some years is occasionally observed. It may complicate also—though less frequently—other spinal affections, such as myelitis of the lateral columns and injuries of the cervical cord. In Friedreich's hereditary ataxia and similar forms of family afflictions (Sanger Brown) it has been noted as a frequent incident. Atrophy of spinal origin is always bilateral.

In a moderate proportion of cases of progressive optic atrophy no cerebral or spinal cause can be established, although many of the patients present distinct neuropathic tendency, revealed either by their own antecedents or by the family history.

The disturbance of sight in optic atrophy may consist mainly in failure of central vision or in narrowing of the visual field, or it may depend on both factors. It is not possible to determine the cerebral, spinal, or idiopathic origin of optic atrophy by visual tests alone, except in cases secondary to retrobulbar axial neuritis (see XIV., 6) or in affections of the chiasm (see XIV., 5).

XIV. Amaurosis; Amblyopia; Hemianopsia.

The present paragraph is to include all those instances of blindness and of impaired sight which are not due to intra-ocular disease, or to lesions visible ophthalmoscopically, at least at the start. The causes are either affections of the optic nerves, diseases of the nervous system, or systemic morbid conditions. Amaurosis of cerebral origin may, in certain instances, be associated with optic neuritis, but this condition is but a complication in such cases, and does not by itself account for the blindness. In default of objective signs, the location of the trouble must be determined by testing the vision in the centre and in the periphery of the retina, by measuring the visual field for white and colors, and by taking into consideration the pupillary symptoms and the condition of the ocular muscles, of course, with due reference to any nervous or systemic phenomena.

1. Congenital poor vision, but with perfect visual field and normal color-sense, is quite common in an eye more hypermetropic or more astigmatic than its fellow. Occasionally patients discover this stationary defect only late in life. To what an extent such an eye loses still further in sight by non-use, in case of strabismus, is an open question.

2. Sudden loss of sight in one eye may occur from compression of the optic nerve, by traumatic fracture of the orbital walls, by orbital hemorrhages and phlegmons. Gradual blindness can be due to slow compression by tumors and hypertrophic growth in the orbit, or of the sphenoid bone. In these cases the ophthalmoscope shows optic atrophy after the lapse of weeks.

3. One-sided transient blindness has been attributed in some instances to reflexes from carious teeth of the same side. The cases are, however, few in number and mostly not of convincing character. Other instances of so-called reflex amaurosis attributed to neuralgic affections of the fifth nerve or sensitive cicatrices on the face, are perhaps better substantiated, but are also rare. Ziem, Berger (and a few others) have reported unilateral amblyopia with restricted field of vision in suppuration of the maxillary or of the frontal sinus.

4. Unilateral so-called *crossed* amaurosis of cerebral origin has been described by Charcot, in cases of apoplexy or embolism in the posterior part of the internal capsule of the other side of the brain, together with anæsthesia of half of the body (on the side opposite the lesion). But in these cases there was also concentric limitation of the visual field, and impaired color perception on the part of the other eye (on the side of the lesion). In other cases the blindness was not complete, but the impairment of sight was simply more intense in the opposite eye, but of the same character as in the less involved eye. No anatomical explanation can at present be given of these seemingly paradox observations.

Very similar to these visual troubles due to organic cerebral lesions are the eye symptoms in hysteria. The most characteristic form is unilateral amaurosis (generally with normal pupillary reaction), or amblyopia with concentrically constricted visual field and color-blindness, or restricted color-fields. The area sensitive to blue is often smaller than the field for red (contrary to the normal state). The affected eye corresponds to the side of the hemianæsthesia, if present, or to the side of the ovarian tenderness. Often the other eye, too, has a constricted field with diminished color-sense, but good central vision.

In the so-called traumatic neuroses, the hysterical or neurasthenic conditions following sudden injuries, subjective failure of sight is but rarely noticed, but very frequently the visual field of both eyes for white and colors is found concentrically narrowed on testing. It has been noticed in such instances that the retinal periphery is quickly fatigued, so that in successive perimetric tests the visual field contracts during the examination.

5. Bilateral amblyopia is necessarily produced by all the causes mentioned in " XIII., arts. 7 and 8, which lead to atrophy of the optic nerves, while at the very start it is sometimes impossible to recognize the atrophy ophthalmoscopically, at least with certainty. If in these cases the patient complains of one eye only, careful tests will still reveal a slight impairment of the sight, color-sense, or visual field of the other eye.

In cases in which both optic tracts back of the chiasm, or the posterior region of the chiasm itself, are injured by pressure of tumors or apoplectic effusions, or by hydrocephalic bulging of the floor of the third ventricle, the atrophy may not reach the intra-ocular end of the nerve until after the lapse of months. Yet there may be bilateral blindness or amblyopia. The seat of the cause is suggested in these instances by either symmetrical or homonymous sector-shaped restriction of the visual fields of both eyes (see explanation under the head of Hemianopsia).

6. Bilateral impairment of central vision with normal or very slightly constricted visual field may be due to retrobulbar neuritis. The diagnosis is based on the detection of a small oval central scotoma for colors, at first only relative for red and green, later on absolute for these colors and sometimes even for blue, with, however, almost normal color-sense in the periphery of the field. The lesion consists of neuritis limited to that bundle of fibres of the optic nerve which supplies the macular region, and it extends throughout both nerves from the eyes to the chiasm (axial neuritis). If not checked this inflammation leads ultimately to barely visible atrophy of the temporal half of the optic disk. Sometimes, but rarely, there is a slight diffuse cloudiness and congestion of the papilla from the start; occasionally there are small retinal hemorrhages.

The most common causes of retrobulbar neuritis are chronic alcoholism, tobacco-poisoning, or the joint influence of both agents, or diabetes mellitus. Almost the same form of optic neuritis may occur also in the course of multiple sclerosis of the brain, sometimes, however, with more diffuse involvement of the optic nerve. Lead-poisoning, too, may lead to the same form of retrobulbar neuritis, although more commonly the lead neuritis involves the entire area of the optic nerve. There is, besides, a so-called idiopathic retrobulbar neuritis, the cause of which cannot always be detected by clinical analysis, though menstrual suppression and exposure to cold are sometimes accused in a vague manner.

7. Sudden blindness, complete or nearly so, of both eyes is (rarely) produced by a diffuse meningitis of the cortex, by cortical œdema, or increased intracranial pressure from tumors. Cortical lesions are the most probable cause in transient blindness after cerebro-spinal meningitis with retained pupillary reaction. Similar observations have been made after scarlet fever, variola, measles, and other infective fevers, sometimes with recovery, sometimes ending in permanent blindness. The nature of the lesion is not known.

A cortical origin, too, we must assume in the transient blindness of both eyes during uræmia, sometimes without loss of pupillary reaction. The cause of the uræmia is kidney disease, generally that which occurs in pregnancy, but also other varieties, as, *e.g.*, that following scarlatina. Transient blindness in periodic spells has been observed as a malarial manifestation. Lead-poisoning has also been known to cause a temporary blindness comparable to uræmic amaurosis. A similar blindness lasting several days has a few times been observed dur-

ing gastric disturbances, disappearing within some hours after the action of an emetic.

There are on record a small number of cases of absolute blindness without intra-ocular cause, observed upon the cessation of a persistent blepharospasm, but followed by spontaneous recovery in every instance.

8. Complete, though transient blindness, or, in less severe instances, marked reduction of vision, has been observed after large doses of quinine. There was marked pallor of the optic disk and narrowness of the retinal vessels. When sufficient sight had returned to measure the visual field, it was found enormously restricted, and in some of the instances it did not regain its full extent. A similar affection has been known to follow an overdose of salicylate of sodium.

9. A few instances have been reported of sudden interference with sight, not due to any actual diminution of visual acuity, but to inability to interpret the visual perceptions, although the mind was otherwise not disturbed (Wilbrand[32]). The condition has been termed psychic blindness and referred to lesions of the occipital cortex. The same condition has been noticed rather often in general paresis of the insane, but on account of the mental failure of these patients it is more easily overlooked.

10. Hemianopsia, or loss of one-half of the visual field of both eyes can only be produced by a lesion of the optic paths situated somewhere between the chiasm and the occipital cortex. It is either homonymous, involving the internal half of the field of one eye and the external half of the other, or it consists in loss of either the temporal halves or the nasal halves of the field of both eyes.

Homonymous hemianopsia is often described wrongly by the patient as failure of the eye on the side of the blind half of the field, and in such instances the nature of the disturbance is only recognized on perimetric measurement. The central vision is generally perfect. The onset is nearly always sudden. Since either optic tract supplies fibres to the external half of the retina of the same side, and to the nasal half of the retina of the opposite eye, the loss of one-half of the field of vision can only be due to a lesion of the optic fibres back of the chiasm and on the *opposite* side of the brain (see article "Visual Centres," by the writer, in Vol. VII. of this work). If the nerve-path involved be the optic tract in its continuity or at its central termination in the external geniculate body, the pulvinar of the thalamus opticus, or the anterior corpus quadrigeminum, the vertical line separating the blind half from the intact part of the visual field runs exactly through the point of fixation (fovea centralis). Wernike has pointed out that in these cases the pupils will respond only if light is thrown into either eye from the perceiving side, while they remain immobile when the light is situated on the blind side (Wernike's hemiopic pupillary reaction). The lesion producing this hemianopsia may be a hemorrhage or hemorrhagic cyst, a focus of softening or a tumor, on the opposite side of the brain, in any locality where it can involve or compress the optic tract or its central termination.

If the lesion is situated in the occipital lobe, involving either the cortex or the white fibres which connect the cortex with the termination of the optic tract, the hemianopsia does not always extend quite up to the point of fixation, but may leave an area of a few degrees in width intact on the blind side of the fovea centralis. This was illustrated in a unique case reported by Foerster,[33] in which left hemianopsia of cortical origin supervened in a man who had previously a right hemianopsia, likewise due to cortical lesion, and who still retained a central area of about three degrees with good sight.

Hemianopsia of cortical (or subcortical) origin is further distinguished by the pupillary reaction when the light is on the blind side, as well as on the intact side of the field, since the lesion does not involve the reflex circuit of the pupillary fibres. The lesions found in the occipital cortex in a number of reported autopsies of cases of hemianopsia were generally foci of softening, less often effusions of blood or circumscribed tumors, involving the *cuneus* or its immediate neighborhood. As the cortical area representing the visual centre is an extensive one, it may be only partially destroyed by disease, and hence the hemianopsia is not always complete, viz., it does not always mean loss of the total half of each visual field, but may be limited sometimes to corresponding sections of each half of the two fields. Cases have also been reported—presumably of cortical origin—in which there was only color-blindness, but not impaired sight for white in the defective part of the field.

11. Hemianopsia involving only the nasal or the temporal halves of both retinæ can be caused exclusively by lesions injuring the fibres in the chiasm itself—tumors of the pineal gland or the sella turcica, localized periostitis, and circumscribed tubercular or syphilitic meningitis.

12. A transient form of homonymous hemianopsia has been termed amaurosis fugax, scotoma scintillans, or ophthalmic migraine. It is popularly known as blind headache. In the most typical cases a peripheral flickering, setting in suddenly, is followed by more or less complete blindness of one-half the visual field, lasting from some minutes up to (exceptionally) over an hour, while the attack is terminated by severe headache. In other instances there may be general amblyopia instead of hemianopsia, or the visual disturbance may be so slight that the patient lays the most stress on the headache. While such spells have been observed in some patients with cerebral tumors, and often, too, in *general paresis* of the insane, they are, on the other hand, a very common complaint, and generally of no grave significance. They are but a form of migraine, and like the latter may be of reflex origin, sometimes from *nasal* anomalies (Hack, and personal observations). In the writer's experience these attacks of fugitive scotoma have also been averted by removing the eye strain of astigmatism, and by relieving *chronic intestinal catarrh*. Whether ophthalmic migraine is occasionally the equivalent of epileptic attacks is an undecided question.

XV. Diplopia.

1. Double sight occurs whenever the two eyes are not directed toward one and the same point—on account of paralysis of an ocular muscle or mechanical interference with the movements of the eyeball. In ordinary concomitant strabismus diplopia is absent, by reason of the mental suppression of the images in the deviating eye, but the double sight can be made manifest by holding a colored glass in front of one of the eyes, or by shifting the retinal images from their usual position by means of prisms.

2. In rare instances two or even more images of the same object are seen by one eye on closure of its fellow (monocular diplopia or polyopia). This may be due to an optic defect—facets of the cornea or lenticular irregularity from incipient cataract—whereby two separate retinal images are formed. Such diplopia is stopped by looking through a pinhole in a screen. But monocular diplopia—not of optic origin—has also been observed in pure *hysteria*, and in the hysteria complicating organic brain disease.

XVI. External Muscles of the Eye (and Levator Muscle of the Lid).

Strabismus, or the deviation of an eye from the position necessary for single binocular vision, is either concomitant or paralytic. The significance of these two forms is entirely different. The former is due to abnormal tension of one of the recti muscles, while the latter is caused by paralysis of one or more ocular muscles.

1. In concomitant strabismus the deviation of the eye is practically the same toward whichever direction the patient looks, and the deviation remains the same whichever eye the patient uses for fixation (with rare exceptions). The patient may either depend on one eye exclusively (usually the better one) for vision, or he may use alternately either eye. The strabismus is more commonly

constant; sometimes, however, it is periodic. The causes of concomitant strabismus are usually intra-ocular. As a rule (but not without exceptions) convergent strabismus is associated with hypermetropia and divergent squint with myopia. Frequently, but not necessarily, the deviating eye is the weaker one. An eye whose vision is enfeebled by corneal opacity, or intra-ocular disease, is apt to turn outward. Convergent strabismus of hypermetropic eyes sometimes comes on suddenly during childhood, especially after febrile diseases. In such cases the patients complain for a time of double sight without paralysis of any ocular muscle. As a rule, diplopia is not observed in concomitant strabismus.

2. Paralytic strabismus always causes an annoying diplopia. The paralytic deviation of the eye and the resulting double sight increase quantitatively when the eyes are turned in the direction of the weakened muscle, and diminish or disappear when the eyes are turned in the opposite direction. In paralytic strabismus the unaffected eye is used for fixation naturally,* and if it be covered and the affected eye be directed toward a given point, the so-called secondary deviation of the normal eye is greater than that of the affected eye. The trouble may vary from slight paresis to absolute paralysis of one or more muscles.

3. Paralytic squint may be simulated by mechanical hinderances to the movements of the eyes, such as tumors in the orbit. The elongation of the eyeball in high myopia and its protrusion in exophthalmic goître may interfere with the converging power mechanically, but this condition is not due to a paralysis. The only (and rare) cause known to damage the eye muscles directly is *trichinosis*.

4. The lesions causing paralysis of the ocular muscles may involve the motor nerves in their course through the orbit, in their intra-cranial portion, at their nuclei in the basal gray substance from the third to the fourth ventricle, or possibly in the paths connecting the nuclei with the cerebral cortex. The seat of the lesion can be diagnosticated only by the careful consideration of all the symptoms presented by the case, and not always with certainty. It must be remembered that while the fourth and the sixth cranial nerves supply only one muscle each (viz., the superior oblique and the external rectus), the motor oculi innervates the superior, inferior, and internal recti and the inferior oblique muscle as well as the levator of the lid and the sphincter of the iris, and that all these fibres of the third nerve are united in the trunk but separated at the central termination as well as at the peripheral distribution. Both anatomical reasoning and clinical observations show that isolated paralysis of either the pupil, the lid, or the three recti together (viz., superior, inferior, and internal) can only be of central origin, but that a simultaneous involvement of all the muscles controlled by the motor oculi is more likely to be due to a lesion of the trunk of the nerve. It has, however, been learned that isolated paralysis of the internal rectus may be of peripheral origin.

5. Many of the cases of paralysis of the internus or externus muscles cannot be referred to any constitutional cause, and are usually described as rheumatic, but without any proof of their rheumatic origin. The writer[34] has ascertained that many such paralyses are preceded by severe acute coryza, and are evidently due to extension of infection from the *nose*. Orbital causes of paralysis are represented by traumatism, fracture of the walls of the orbit or of the rim of the sphenoid fissure, phlegmon, and tumors.

6. The intra-cranial part of the motor nerves may be compressed by *hemorrhages, meningeal exudations, tumors* of the brain or skull, or *thrombosis* of the cavernous sinus, and in rare instances by aneurismal basilar arteries. Quite common are paralyses, usually multiple, from localized *syphilitic basilar meningitis*. The nerves are also implicated often in fractures at the base of the skull.

7. The nuclei of the motor nerves of the eye may be injured to a greater or less extent by hemorrhages, softening, or tumors, especially syphilitic or tubercular, involving the region between the basal ganglia and the medulla oblongata. There occurs, besides, a progressive ophthalmoplegia externa, due to disease limited to the nuclear gray substance, sometimes of syphilitic origin, in other cases due to a non-syphilitic polio-encephalitis inferior. Disease of the nuclei may also occur before birth, as isolated or multiple paralyses of the lid elevator and the recti muscles are not rarely congenital.

Clinical evidence and scant autopsies have shown a nuclear origin as well in the isolated and often transitory paralyses which are often observed in *syphilis*, in *tabes* (where they may be one of the earlier symptoms), in *multiple sclerosis*, in *diabetes*, in *purpura hæmorrhagica*, in *poisoning by lead, tobacco, carbonic oxide*, and *ptomaïnes* of spoiled meat. The same may be said of the relatively infrequent paralyses following diphtheria (while paralysis of the fibres of the third nerve supplying the ciliary muscle is so common from this cause). Transitory or even permanent palsies of ocular muscles have been known to follow the acute exanthemata, various infectious fevers, and especially *influenza*. Within some years comparatively many cases have been reported of *periodic paralysis* of the *motor oculi* nerve, sometimes complete, sometimes only limited to some of its branches. The spells are preceded by headache, last some days or weeks, and then cease entirely, but return after irregular intervals. The cause is probably central.

8. Of lesions above the nuclei of the motor nerves but little is known in relation to ocular paralysis. Isolated ptosis—paralysis of the levator muscle of the lid—has been observed in disease of the posterior region of the parietal cortex of the opposite side. It is probable that the transitory and often variable pareses observed occasionally in hysteria are due to cortical influences. A few instances of paralysis of associated movements of both eyes (upward, downward, or lateral), but without paralytic strabismus, have been observed (O. Bull),[35] which on clinical evidence can only be referred to disease of the hemispheres of the brain.

9. A not uncommon symptom of localized cerebral disease, especially apoplexy or softening, is conjugate deviation of both eyes to one side, attributable to spasm rather than to paralysis of the internal rectus of one eye and the external rectus of the other. It may be due to either irritative or destructive lesions of the hemispheres or of the basal region, especially the pons. Landouzy states that turning of the eyes toward the paralyzed side indicates a destructive lesion in the neighborhood of the pons, while hemispherical injury causes the eyes to turn away from the palsied side, but that in case of contractures the deviation toward the convulsed limbs means hemispherical, and away from the side of the spasm, pontine irritation.

10. Nystagmus—rhythmic oscillation of the eyes—is generally congenital, or acquired during early childhood in connection with any intra-ocular disease or defect causing imperfect sight. But if it originates after early infancy its significance is entirely different. The acquired nystagmus is a comparatively frequent affection in coal-miners, brought on by the constrained position and the inevitable fatiguing turning of the eyes to one side, perhaps also by the insufficient illumination. If acquired without this provocation it is symptomatic of either malformation of the skull and brain or of *multiple sclerosis*, of hemorrhagic or embolic *foci* in the *thalamus opticus*, the *fourth ventricle*, the *restiform body*, or the *cerebellum*, of *infantile encephalitis*, or of *Friedreich's* hereditary form of *ataxia*.

XVII. Orbit.

1. Hemorrhage into the orbital cavity is quite rare from any but traumatic causes. In the latter case, if the force has not been directed against the orbit itself, the hemorrhage denotes *fracture* of the base of the skull. Severe coughing fits, *scurvy*, and *vascular degeneration* have caused effusion of blood in rare instances. Gaseous infiltration of the orbit—emphysema—can only hap-

* Except when its sight is much less than that of the other eye.

pen from violent expiratory efforts after a fracture of the wall has established communication between the orbital and nasal cavities.

2. Orbital affections may be simulated by empyema of the frontal or of the ethmoid sinus. But these suppurations can also extend into the orbital cavity, causing phlegmon or abscess. Other causes of orbital phlegmon may be *facial erysipelas* or *furuncles*, orbital traumatism and infection, *thrombosis* of the *cavernous sinus* or extension of a *suppurative meningitis*. Phlegmons of *pyæmic* origin have been observed, in surgical pyæmia and in severe infectious fevers. Inflammation of the sheath of Tenon occurs sometimes after severe coryza, and has been seen often secondary to *influenza*. Caries of the orbital wall may be due to *syphilis*, *tuberculosis*, or infection by pus microbes.

3. Exophthalmus, or protrusion of the eyeball, is caused by any tumor or tumefaction in the orbital cavity and is somewhat simulated by the prominence of highly myopic eyes. Exophthalmus forms a prominent symptom of Graves' (or Basedow's) disease—*exophthalmic goître*. There are, however, rare cases of this disease without exophthalmus.

Enophthalmus—the receding of the eyeball into the orbit—is a common appearance in all wasting diseases.

BIBLIOGRAPHY.—The numerous observations upon which this review is based are scattered throughout ophthalmological and neurological literature, and are summed more or less completely in the larger text-books on the eye and on the nervous system. Many details will be found in the different ophthalmic contributions to this REFERENCE HANDBOOK, especially the article by Dr. Moore on "Medical Ophthalmoscopy," in Vol. V. Very complete accounts of the connection of the nervous system, with optic nerve and retina can, be found in Leber's classical treatise in vol. v. of Graefe and Saemisch's *Handbuch der ges. Augenheilkunde*, 1877, and in the articles on the retina (1887) and optic nerve (1888) by De Wecker, and on amblyopia by Nuel (1887) in De Wecker and Landolt's "Traité complète d'Ophthalmologie." Very full also is the part on muscular anomalies by Landolt and Eperon in the same work. Reference should also be made to the "Medical Ophthalmoscopy" by Gowers, 1879 (and second edition in 1881). Good *résumés* of the same subjects are given by Mauthner, "Gehirn und Auge," 1881, and "Die Nuclearlaehmungen der Augenmuskeln," 1885. The relations between the uterus and the eyes are summed up by Cohn in "Uterus und Auge," 1890. On the connection between the nose and the visual organ full references can be found in Berger, "Rapports entre les Maladies des Yeux et celles du Nez et des Cavités voisines," 1892, and in H. Gradle, "The Etiological Relations of Nasal Diseases to Affections of the Eyes," in "Transactions of the Ophth. Section of the Am. Med. Assn., 1892," (and *Journal of the Am. Med. Assn.*, September 10, 1892). The importance of syphilis is well portrayed in Alexander's "Syphilis und Auge," 1889.

A complete *résumé* of eye symptoms in general pathology was first brought out by Foerster, in Graefe and Saemisch's *Handbuch der ges. Augenheilkunde*, vol. vii., 1877. In 1885 Jacobson wrote his short but thorough monograph, "Beziehungen der Veränderungen und Krankheiten des Sehorgans zu Allgemeinleiden und Organerkrankungen," in which—as in the present article—the relations are classified from the ophthalmic standpoint, while tabulation from the medical point of view is again the plan in Berger's large compilatory work, "Les Maladies des Yeux dans leur Rapports avec la Pathologie générale," 1892. The latest review of the subject is the volume by Knies, "Die Beziehungen des Sehorgans und seiner Erkrankungen zu den übrigen Krankheiten des Körpers," 1892. *H. Gradle.*

FALMOUTH. A popular sea-side resort in Cornwall, England. Falmouth, although nine hours by rail from London, is a fashionable sea-side resort, which has lately become quite prominent. The harbor is one of the finest in England, and the sandy beach is very attractive. The climate, though humid, is mild and agreeable. Bathing is the chief attraction. Invalids of various kinds live there in winter and spring, owing to the climatic and sanitary advantages of the place. *Edmund C. Wendt.*

FEL BOVIS. The action of ox-gall in assisting the absorption of fats and oils, and its aid in maintaining intestinal antisepsis, has suggested its use as a proper means of treating typhoid fever. Dr. Adolph Zea reports the result of ten cases in his own wards, and forty-eight cases treated by medical friends, as very gratifying. His method of conducting the case is as follows: If seen early, a dose of calomel is given to relieve the digestive tract of its contents; alcohol in the form of whiskey is given at first as a stimulant, and, if additional stimulation is required, strychnine, caffeine, ammonia, camphor, or small doses of quinine; dilute muriatic acid in large quantities of water as a beverage, and fel bovis purificatum siccum, in doses of two to four grains, three to six times a day in pill form or capsule. The diet consists of fluids—milk, gruel, beef-tea—in small quantities frequently given. The milk should always be boiled, but may be given hot or cold according to the wish of the patient. Preparations of beef extracts and juices may also be given.

The benefit of this treatment is shown in a reduction of the temperature after the drug has been given for a few days, and a freedom from all distressing abdominal symptoms and complications. Convalescence is also thought to be more rapid than under any other line of treatment.

It is urged that if bile is essential in health, it is still more so in such a condition as enteric fever, when the functions of all the organs are in abeyance and the normal secretion of bile, so much required, is lacking. It is uncertain how it acts, whether by passing direct from the stomach into the intestines, or whether it is first absorbed and then secreted as human bile. If the article is pure and not altered by age it is perfectly unirritating and may be given without the fear of its causing any unfavorable results. Whenever pain, vomiting, or any symptoms of gastric irritation arise, it is due to the presence of proteid matter and other impurities in the drug, which have imparted the poisonous properties.

W. H. Porter contributes, in Merck's *Bulletin*, July,

1890, an article on the properties of ox-gall. He has used it in great quantities for over ten years, giving as much as twenty-five or thirty pounds during a year. He insists upon the necessity of procuring good preparations, both free from impurities and not spoiled by exposure to the atmosphere. He recommends that only the purified inspissated bile should be used.

The physiological action of ox-bile is summed up by him as follows: 1. It acts on the fats and promotes their absorption by the lacteals. In all forms of milk diet he thinks that two grains of the purified gall in capsules should be given before the diet is commenced in the morning, and repeated during the day according to the quantity of milk ingested. 2. It contains a diastatic ferment and has an important action in the conversion of starch into glucose. 3. It promotes a normal peristalsis of the intestine which favors absorption and prevents constipation. 4. The bile-acids stimulate the minute muscles of the villi, the contractions of which force the contents of the lymph-sacs onward and favor absorption. 5. The presence of the bile stimulates the activity of the epithelium and promotes a secretion of fluid from the follicles. 6. It prevents putrefactive changes and may be looked upon as nature's chief internal antiseptic. 7. It aids the final solution of albuminoids and their conversion into the diffusible peptones. *Beaumont Small.*

FELIXSTOW. A rising spa on the Suffolk coast, England.

Location.—Felixstow Spa is about twelve miles from Ipswich, and two and a half hours from London. Having a southerly aspect, comparatively dry air, a bracing climate, a fine beach, and a chalybeate spring, it is growing in popular and professional favor. In *The Lancet* of November 12, 1892, Dr. Macnaughton Jones gives the following particulars of the place:

"Facing the German Ocean, between Harwich on the south and Bawdsey at the mouth of the Deben River on the north, Felixstow beach occupies an amphitheatre which has at one point of the crescent Landguard Fort, commanding the entrance to Harwich, and at the other a picturesque villa perched just above the cliffs of red crag and London clay that bound this part of the coast and over which there is a delightful walk to Felixstow ferry. The famous golf grounds and the well-known golfing club—the links of which are splendidly placed on the side of the Deben river, close to the sea, about two miles from the eastern side of the town—attract many visitors. The capital bathing beach and the safe sands render Felixstow a typical place for children, and each year it is growing more in popular favor as a children's holiday resort. Dr. Taylor, having tested personally and with others the medicinal properties of the spa, was induced to try its aëration by artificial means, hoping thus to get rid of the smell and unpleasant taste due to the decomposition of the pyrites which is found in the London clay of the soil. In this he has been most successful. The taste reminds one of the Weinbrunnen spring at Schwalbach—sparkling and mildly chalybeate."

Analysis.—According to Dr. Frankland, one hundred thousand parts of the water yield the following ingredients:

	Parts.
Total solid residue dried at 130° C.	85.30
Lime as carbonate	11.76
Magnesia as carbonate	2.16
Total magnesia as carbonate	5.78
Soda	22.25
Potash	1.21
Chlorine	30 44
Sulphuric anhydride	3.40
Silica	1.51
Alumina and peroxide of iron	0.11
Organic carbon	0.063
Organic nitrogen	0.019
Ammonia	0.070
Nitrogen as nitrates	0.0
Phosphoric acid	0.0

These constituents are probably combined in the water in the following manner:

	Parts.
Carbonate of lime	21.00
Carbonate of magnesia	4.54
Sulphate of lime	4.01
Sulphate of magnesia	1.52
Chloride of magnesium	7.36
Chloride of sodium	39.60
Chloride of potassium	1.92
Silicate of sodium	3.07
Alumina and peroxide of iron	0.11

Indications.—According to Dr. Jones, the constitution of such a water would justify the belief that it must prove of use in cases of atonic dyspepsia, and as a mild purgative, from the sulphate and chloride of magnesia which it contains; both used internally and as a bath such a spa should prove of efficacy in gouty rheumatism and muscular neuralgias. A spring which can yield an unlimited supply within a few yards of the beach of one of the most salubrious of English sea-coast resorts, in a neighborhood with a singularly dry climate and a soil that quickly absorbs moisture, free from moist exhalations, and that by its situation is protected from the severity of the east winds, is well worth developing. The drinking-water of Felixstow is singularly pure, being drawn from an artesian well which is sunk in the chalk.

Accommodation.—There are plenty of good apartments, charmingly situated villas, and an excellent hotel, which is beautifully situated and within a few hundred yards of the spa. There are many pleasant drives in the vicinity (Jones). There is a "Spa House," resembling somewhat a German *Kursaal*. There is also a large "Convalescent Home." *Edmund C. Wendt.*

FEVER. Recent investigations have somewhat modified our views of fever, particularly as regards its dangers. They have taught us, among other things, not to base the prognosis of a disease upon the height of the fever that is present, to the neglect or exclusion of other symptoms. The term fever is here limited in its signification to elevation of temperature, although it is still frequently employed to designate a group of symptoms of which elevated temperature is one of the most prominent and one of the most important.

Elevation of temperature and increased heat-production are not synonymous terms, neither is the one a measure of the other. The temperature curve, as described by the record of thermometric readings, serves but to denote the balance between opposing tendencies, of which heat-production and heat-dissipation are the most important, but possibly not the only factors. Macalister has aptly said, "The constancy of the temperature of the body in health, under widely varying internal and external conditions, is a fact so familiar that we have ceased to wonder at it; yet it rests upon a perpetual balance of opposing tendencies which is as mysterious and as beautiful as anything in our frames." And the same may be said of the temperature in fever, except that the conditions are abnormal. No one, perhaps, has given us a more lucid explanation of the nature of fever than the author referred to in his Gulstonian Lectures of 1887, which have done much to mould the thought of succeeding years.

Macalister[1] considers the fever mechanism under three heads, namely, first, a thermogenic, or heat-producing mechanism; second, a thermolytic, or heat-dissipating mechanism; and third, a thermotaxic mechanism, whose office is to exert a controlling or equalizing influence upon the mechanisms for the production and dissipation of heat. Our definite knowledge of these three mechanisms is by no means equal, but like that of most physiological phenomena, grows less as we ascend farther from the lower animal kingdom. Our knowledge therefore of thermolysis is comparatively full, for this mechanism is found even in the cold-blooded animals. We know less of thermogenesis, and have only recently learned anything of its connection with the nervous system; while we have little more than inferential knowledge of thermotaxis, which is believed to reach full development only in the mature human being.

Thermolysis.—Thermolysis, or the mechanism of heat-dissipation, is too well understood to justify extend-

ed description in this place. It acts chiefly through the blood-vessels and sweat-glands of the skin. It is under the supervision of the vaso-motor centres of the medulla and spinal cord. These centres are perhaps of two kinds, vaso-constrictor and vaso-dilator in character. A certain part of heat-dissipation, amounting, perhaps, to twenty per cent. of the total heat-loss, is accomplished through the respiratory organs, and these are also under the control of a centre in the medulla oblongata, with, it is believed, a motor and inhibitory action. It has further been determined that these centres governing thermolysis are susceptible to elevation of temperature in such a manner that the result is an increase of the discharge of heat from the body. This mechanism is believed to be a common property of the animal kingdom, being found well developed in the cold-blooded animals as well as in the warm.

THERMOGENESIS.—The muscles are the seat of heat-production, the "thermogenic tissue par excellence." They produce four-fifths of the body-heat in health, and perhaps a larger ratio of it in pyrexia. The remaining fraction is supplied by the secreting glands and the alimentary canal during digestion. As secretion and digestion are at a low ebb during fever, this fraction becomes less, and the muscles remain almost the sole producers of heat.

Modern investigations have but confirmed the old doctrine that the formation of heat is materially increased in fever, that the process of heat-formation in the muscles is chemical in nature, and for the most part a process of oxidation (combustion). Oxygen is absorbed and carbonic acid is discharged. The absorption of oxygen and the discharge of carbonic acid do not always, however, bear a constant relation to each other. A measure of the one cannot be used for the estimation of the other in a given case. The more recent investigations of Finkler and others have yielded results differing but little from those obtained in 1877 by Colasanti. The latter observer found the average increase in the amount of oxygen absorbed in fever to be 18 per cent., and the increase in the excretion of carbonic acid 24 per cent. Finkler found, under circumstances fairly similar to those of Colasanti, that the increase of oxygen absorption was 13.8 per cent., and of carbonic acid discharge 15.3 per cent. He found, further, that the increased absorption of oxygen kept pace with the stage of the fever; that it increased as the fever rose, remained stationary in the fastigium, and declined with defervescence. The highest percentage he found was 36.6 per cent. of oxygen increase, and 37.6 of carbonic acid lost. It is admitted by all investigators, however, that we have no means of determining with absolute precision the amount of oxygen which is absorbed in fever. This fact is largely accounted for by the uncertainty which must exist as to the respiratory quotient, or the ratio of oxygen that is used in the production of carbonic acid in respiration. It is probable, too, that, just as in health, a certain part of the oxygen that is absorbed in fever is used in the production of other combinations than carbonic acid, particularly in the production of water. But the respiratory quotient is admitted to be lower in fever than in health, since in fever only fats and proteids are oxidized. Colasanti [2] and Lilienfeld,[3] while admitting this fact, assert that the respiratory quotient in fever does not materially differ from that of the same animal in health, under the conditions of nutrition which are present in fever. Finkler [4] thinks the reduction of the respiratory quotient more rapid than occurs in hunger, owing to the greater rapidity of oxidation that takes place. All agree, however, that the oxidation-products in fever are the same as those of health, and that additional products, if formed, are produced in very small amounts. According to Regnault and Reiset,[5] a fourth to a third of the absorbed oxygen, in hunger, is available for combination with hydrogen to form water. If, as is claimed by Colasanti and Lilienfeld, the same ratio exists in fever, heat-production ought to be proportionate to the amount of oxygen absorbed. But if, as Regnard [6] asserts, the respiratory quotient is always very markedly reduced in fever, and a larger amount of oxygen is available than in health for the oxidation of hydrogen, the increment of heat-production should be still greater; for a greater amount of heat is produced by the same amount of oxygen, when employed for the oxidation of hydrogen, than when it combines with carbon. And another source of variation lies in the fact that the same quantities of hydrogen and carbon, in their oxidation, yield varying amounts of heat, according to the chemical compounds in which they are contained, and we cannot say positively that the compounds oxidized are the same in fever as in health under like conditions of nutrition (Welch).[7]

Ord [8] has given us yet another, and a very ingenious, hypothesis in reference to a source of at least a part of the fever-heat. He suggests that chemical processes occur in the body by which, in health, heat-energy is stored up or rendered latent, as in the up-building of tissues. Since, therefore, tissue-formation is in abeyance during pyrexia, he argues that the heat of the body may be increased not only by processes of disintegration, but as well by the persistence, in the form of heat, of energy which, under normal conditions, would have taken another form. But, as Welch remarks, the amount of energy appropriated in the form of heat by these constructive processes bears only a very small ratio to the total heat-energy set free by heat-producing processes, so that their cessation would not bring a very large increment to the heat of the body. Welch,[9] while he does not attach much importance to figures purporting to express the actual heat-production in fever, believes that we are justified in drawing one conclusion from the results of direct and indirect calorimetric observations: "This is, that while an individual in fever produces more heat than he would in health under similar conditions as to food and muscular movements, he does not produce necessarily in fever more heat than he would in health on a full diet. And it is certain that he usually produces far less heat in fever than he often does under circumstances which normally increase heat-production, such as a cool environment and muscular exercise. . . . That in health vastly increased heat-production may occur with comparatively little change of temperature, is, of course, due to the fact that the dissipation of heat is proportionately increased. It is self-evident, and, so far as I know, has never been disputed, that in fever the equilibrium is so disturbed that heat-loss does not correspond to heat-production, as it should in health."

Many very interesting experiments have been made with a view to determine the relation, if any, which exists between heat-production and work-production in the muscles. It has been found that a muscle stimulated to action by an electric current produces both motion and heat, but that under long-continued stimulation the muscle becomes fatigued as a heat-producer much sooner than as a work-producer. The heat-producing function may even be abolished through fatigue without total or even very marked loss of the power of work-production. Cold is also capable of depressing or abolishing thermogenesis without notably affecting the motor function. The two functions are further distinct as to time, for while muscle-action causes heat-production, it is not necessary to it. A muscle which is at rest, so far as motion is concerned, continues to be a heat-producer so long as its nutrition and innervation remain intact. In other words, heat-production is constant, work-production intermittent. There cannot, therefore, be any constant relation between muscle-force and heat-production. Drs. Mead Smith, Macalister, and Lukjanow [10] conclude, from their experiments in Ludwig's laboratory, that the two processes are independent of each other in nearly all features, and in all such external relations as fatigue, exhaustion from inanition, rest, and temperature.

Macalister, basing his conclusions on his own experiments and those to which reference has just been made, says: "The conclusions I have adduced, and especially those relating to the power of recovery in a fatigued muscle, under the influence respectively of rest and of the blood-supply, point to the conclusion that the two metabolisms are in some way different; in other words,

that the 'contractile stuff' in the muscle is not the same as the 'thermogenic stuff.' Both of them are stored up in the muscle; so far as function is concerned they *are* the muscle. The store of each can be exhausted by repeated stimulation, but in some cases the thermogenic store sooner than the other. Both can be upbuilt again by the circulating blood, but in some cases the contractile store sooner than the thermogenic. Both the metabolisms are affected by cold, but the thermogenic much more intensely than the contractile. We know little of the chemical changes involved in either form of metabolism. Oxygen is taken up in each and carbonic acid is discharged, but the processes passed through between these terminal stages are much more complex than mere oxidations. The evidence rather goes to show that it is the living substance, as a whole, contractile stuff and thermogenic stuff, which is continually being decomposed and as continually recomposed by the blood."

The independent character of these two functions of the muscles has suggested the probability of an independent nervous control over each function, but no separate nerve-supply for the government of them has yet been discovered. It is believed by some investigators that thermogenesis is under a motor and inhibitory nervous mechanism similar to that which governs the thermolytic and so many other mechanisms with which we are familiar; but nothing is known of the path by which these motor and inhibitory impulses reach the muscles, unless they are conveyed by the same nerve-trunks which carry the impulses for the control of the work-producing function. Probably they are in some manner transmitted by the motor fibres, or if a special nerve-channel exists, it may probably be so associated with the former as to be undistinguishable from it. Mead Smith attempted to demonstrate the existence of separate fibres for thermic and motor impulses by means of the injection of curare, but without success. Mosso,[11] however, found that by the administration of moderate doses of this drug the motor nerve-endings may be completely paralyzed without obliterating the sensibility of the thermic nerves; he also found that the injection of strychnia into animals thus moderately curarized produced elevation of temperature, but no excitation of the motor function of the muscles. The centre which controls thermogenesis has been located by nearly all investigators in the corpus striatum. The evidences which have led to this conclusion have been both clinical and experimental, the former class beginning with Sir Benjamin Brodie's case of fracture of the cervical vertebræ and spinal-cord injury; the latter class with Bernard's experimental sections of the sympathetic in the necks of animals with resultant rise of temperature. Subsequent experimenters, among whom none have been more painstaking and conscientious than H. C. Wood, of our own country, have arrived at fairly uniform results, although differing widely as to details. Following up the experiments of Tscheschichin, this investigator found, by calorimetric experimentation, that an actual increase of heat-production occurs after section of the nerve-matter at the junction of the pons and medulla. From this he concludes that there are situated above this point thermo-inhibitory centres. More definite conclusions have been arrived at in regard to the location of these centres by Ott, Aronsohn and Sachs, Baginsky, and others. Ott[12] concluded that there are four heat-centres in the cerebrum, one in the vicinity of the corpus striatum, one in the caudate nucleus, a third in the anterior inner end of the optic thalamus, and the fourth near the median line between the optic thalamus and corpus striatum. Injury of the centre in the optic thalamus caused the most pronounced rise of temperature. Aronsohn and Sachs[13] found that puncture of the anterior part of the caudate nucleus, near its median convexity, causes rapid rise of temperature, amounting to three or more degrees, and continuing for two or three days, and that electrical stimulation of the same region causes a similar rise of temperature. This was accompanied by increased absorption of oxygen and elimination of carbonic acid and nitrogen. They, therefore, conclude that there is here located a thermo-excitory centre. As further evidence of the existence in the corpus striatum of a nervous mechanism intimately connected with the production of heat, White[14] cites the fact that this body is larger in warm-blooded animals than in cold, and largest in those which are subject to the highest rise of normal temperature, especially birds.

Thermotaxis.—The thermotaxic mechanism to which reference has been made has for its office to maintain a balance between thermogenesis and thermolysis, probably by causing modifications in the action of one or other of these mechanisms, or both. It is supposed to reside in the nervous system, but its precise location is not known. Ott locates it in the cortex in the vicinity of the fissure of Rolando, with some fibres at the base of the brain in some way connected with it; but Corin and Van Benedin[15] deny that any cortical centres are in any way connected with the heat-mechanism, since they were able to remove the hemispheres in pigeons without causing any change of temperature. Probably absent altogether from cold-blooded animals, the thermotaxic mechanism is much better developed in man than in the lower warm-blooded animals, a fact supported by the much greater stability in man of normal temperature. That it is but poorly developed in infants is indicated by the ease with which trifling causes produce marked disturbances of temperature, depressions on exposure to cold, and elevations on the occurrence of slight functional disturbances, as of the digestive organs. White believes that the human embryo is, until quite the late months of intra-uterine life, a cold-blooded animal, depending for its warmth upon that of surrounding media. Welch[16] believes that fever-producing agents must act directly or indirectly upon the mechanism which regulates the harmonious relation of heat-loss to heat-production. Macalister does not limit the production of fever to the disturbance of thermotaxis, but believes that there are three degrees of disturbance ordinarily produced. "Fever necessarily implies (1) a disorder of the thermotaxic mechanism; (2) an excessive production of heat, associated with excessive chemical changes in the tissues, the excessive production being more or less than that of a normal patient in full diet (perhaps oftener less than more), but more than that of a normal patient on fever diet; (3) that the body temperature depending upon the balance between production and discharge, fluctuates as the one or the other is in the ascendant, and is not, *per se*, a true measure of either, or of the consumption of tissue that may be going on. When thermotaxis alone is disturbed, the result is a peculiar rising and falling of the temperature, depending upon variations of production and loss, without the normal controlling influence of the affected centre. This has been termed thermal ataxia. The next degree of disturbance is that which is probably present in ordinary fever, namely, a disturbance of thermotaxis and thermogenesis, resulting in a loss of the controlling influence and an increase of heat-production. With this is associated, as a rule, a stimulation of thermolysis, an increased dissipation of heat. When, however, we have, in addition to the disturbance of thermotaxis and thermogenesis, a diminution of the dissipation of heat, the result is hyperpyrexia. The reduction of heat-dissipation thus produced is supposed to be in great measure a result of the action of high temperature, and to denote an exhaustion of the nervous mechanism controlling thermolysis; it is in part also, no doubt, a result of the action of the toxic matter which is the cause of the increased temperature." Fever, in other words, according to Macalister, is a process of dissolution from above downward, affecting first the centres most recently evolved and therefore most liable to disturbance, and last, those which are most stable (White). In recovery, too, this author maintains, with apparent correctness, that control is regained from below upward. First the thermolytic mechanism is incited to action, which is frequently indicated by the occurrence of more or less profuse sweating. As thermogenesis becomes more and more inhibited the temperature rises less and less high on succeeding days; but until thermotaxis becomes fully established the rhythm of thermogenesis and thermolysis is easily disturbed by such

trifling causes as errors in diet, fatigue, etc., the condition of the convalescent in this regard resembling somewhat that of the infant.

Wood [17] maintains that the cerebral centre is inhibitory in character, its disturbance permitting rather than producing increased thermogenesis. Heat-dissipation he places under control of the vaso-motor centres. In a contribution to the American Association of Physicians he thus recently summarized his theory of pyrexia:

First. "Fever is a disturbance of calorification in which, through the nervous system, heat-dissipation and heat-production are both affected. If there be a fever which is produced by the direct action of a poison, independent of the nervous system, we have at present no proof of its existence.

Second. "Heat-production is regulated by a nervous apparatus of which the knowledge is still imperfect. There is certainly an inhibitory centre which depresses or controls the production of heat. It probably does this by acting on the trophic cells of the gray matter of the spinal cord. It is possible also that there is a centre which, when excited, increases tissue-change, but its existence has not yet been proved.

Third. "Heat-dissipation is regulated through the vaso-motor system, so that vaso-motor paralysis is followed by an enormous loss of animal heat, and, under favorable conditions, by death from cold." [17]

Hanfield Jones [18] adopts a yet simpler view in the supposition that elevation of temperature is a paralytic phenomenon due, as is also the increased heart action and rapid respiration, to a toxic depression of nerve-centres similar in character to the depressant action more easily recognized in the clouding of the intellect and impairment of muscular mobility.

Immediately after the lectures of Macalister, Maclagan [19] published a series of articles on pyrexia and hyperpyrexia. He considers these not as different degrees of the same condition, but as essentially different in their causation. He states two theories of fever, first the combustion theory, according to which there is abnormal activity of the heat-producing process; a second, the neurotic theory, according to which the elevation of temperature is due to the impairment of the inhibitory force which keeps heat-production within normal bounds. He does not regard the two theories as antagonistic, but believes that each has its sphere of applicability. The combustion theory applies to all such specific fevers as malaria, rheumatism, and pneumonia—to all, in short, in which the poisons may be supposed to be micro-organisms, whose morbific action depends upon their organic development. He thinks it probable also that the fever of all inflammations is thus produced, not that all are necessarily due to foreign organisms, but because excessive activity of the minute cellular elements of the tissues may have the same effect on their metabolism as the propagation in them of foreign organisms. The neurotic theory explains probably all cases of hyperpyrexia resulting from non-inflammatory lesions in the nerve-centres, and probably most forms of so-called ephemeral fever.

Austin Flint [20] believes that the cause of fever is twofold, the more important factor being an exaggeration of the chemical changes taking place within the organism which generates the animal heat within normal limits, the other factor being a disturbance of the process of equalization of temperature, which acts mainly through the skin. He believes that the original cause of most, if not of all, the essential fevers is a micro-organism, different in character in different forms of fever. The author does not, however, in this connection enter into a discussion of the theory of nervous supervision over the heat-mechanism.

Causes of Fever.—The study of the etiology of fever has confined itself for the most part to the investigation of the action of ferments and putrid matters when introduced into the circulation, and to the effects produced by the entrance into the organism, experimentally or otherwise, of the micro-organisms of disease and their products. Fever sometimes undoubtedly occurs, however, which is due to the direct impression on the nerve-centres of influences arising in the body, even in the nervous system itself, quite independently of the action of chemical products of any kind.

The chemical agents which produce fever are of two kinds, namely (*a*) those which are a result of metabolisms going on in the organism independently of micro-organisms, and (*b*) those which result from the action of micro-organisms. The former bear close resemblance, if not relationship, to the physiological ferments, or are identical with them. Instances of their action are believed to be seen in the so-called aseptic fever following the receipt of severe injuries and the fracture of large bones, which are removed from infection or are cared for in the most rigidly antiseptic manner. Some of these agents are supposed to exist in small amount in the healthy organism, others to result from the decomposition of extravasated blood or other tissue. The fever of anæmia is also supposed to be, in some instances at least, a result of this kind of intoxication.

The second class of fever-producing agents, resulting from the action of micro-organisms, are of two kinds, agreeing with the pathogenic or non-pathogenic nature of the organisms of which they are the products. The term non-pathogenic is here used in its usual signification, designating micro-organisms which are not capable of propagation within the human body, although in some instances capable of producing disease when introduced into it. Large numbers of these organisms, for the most part saprophytes, reside at times in the body. They exist in great numbers and in great variety in the alimentary canal, into which they gain entrance with the food. The products of their metabolism alone gain access to the circulation, and the fever thus produced, as also its degree and the character of the accompanying symptoms, depend in part upon the amount and the character of the substance absorbed and the character of the organisms producing them, and in part upon the nature of the soil on which the organisms have grown, the character of the environments, etc. Examples of the pyrexia thus induced are abundantly seen in the fever caused by digestive disorders, particularly in children; in the fever which results from the absorption of toxic matters deposited by micro-organisms upon the surfaces of the mucous membranes of the fauces and tonsil, including perhaps some cases of diphtheria; in the elevation of temperature which follows wound-infection; and in many of the cases of poisoning which follow the eating of such unsound food as decayed meat or fish.

Most, if not all, the acute infectious diseases are now attributed to the presence and growth within the body of micro-organisms, the so-called pathogenic bacteria. Fever in these diseases is believed to be due to the chemical products of these organisms, and therefore we attribute the symptom to the organism which produces the poison. Although the organisms exist and grow within the blood-vessels, spleen, lymph nodes, and other glandular organs, few symptoms ever, and fever probably never, result from the direct action of the bacteria. Their chemical products, carried by the circulating blood, act directly upon the centres governing the heat-mechanism in the manner that has already been described.

Comparatively little is known concerning pyrexia resulting from the disturbance of the thermotaxic mechanism by any other than chemical irritants. Instances of it are, however, supposed to be presented in the elevations of temperature occurring in hysteria, in pronounced nervous excitement, particularly of children, and in convalescence. The elevation of temperature which sometimes occurs in convulsions may be regarded as of this character only when the convulsive phenomena are due entirely to nervous excitation in the absence of any toxic influence.

Effects of Fever.—The list of disastrous results which can be attributed to fever has been greatly shortened during the last few years. Formerly nearly all functional disturbances and all tissue-changes which occurred during the existence of a pyrexia were attributed to the elevation of temperature, and so great was the fear of fever that its reduction became almost the

sole object of treatment. A reversion from these views has occurred, however, which is so complete that we no longer look upon an occasional rise of temperature to 104° or 105° F. with much alarm, and there are those who maintain, with probable correctness, that elevation of temperature is one of nature's methods of combating disease—a *vis medicatrix naturæ*.

To determine the effects of high temperature many clinical observations and many experiments have been made by a large number of investigators. Probably the method which has yielded the most satisfactory results has been that of observing the effect of external high temperature on man and animals. By this means we have produced not only the desired elevation of internal temperature, but also the elimination of the influence of toxic elements which must always be taken into consideration when observations are made at the bedside. As a result of the observations referred to, all experimenters agree that a mammalian animal, artificially heated, dies when its temperature reaches 44° or 45° C. (111.2° or 113° F.). The death is preceded by convulsions, is quickly followed by rigor mortis, and is attributed to heart paralysis. Most of the animals experimented upon show signs of illness at a temperature several degrees below the lethal point, and it was inferred by most observers that toxic changes were produced by the increased temperature. But Naunyn reasonably attributes the cause of death, in many of the reported experiments, to the fact that the animals experimented upon were confined in small, ill-ventilated compartments, sufficient alone to cause their illness. By correcting these errors he succeeded in keeping a rabbit alive for thirteen days at an average temperature of 41.5° C. (106.7° F.). Welch,[21] by following Naunyn's suggestion, succeeded in keeping two black rabbits alive three weeks with an average temperature of 41.8° C. (107.3° F.) and 41.4° C. (106.6° F.), respectively. His observations are probably the most accurate that have yet been made. Although the animals lay most of the time stretched out, they took their food greedily and manifested no symptoms of illness. It was found essential to the success of the experiments, however, that the temperature be gradually raised. It was found that no factor is more important in determining the effects of external heat than the animal's power of temperature regulation. Failure of this power (paralysis of the thermotaxic mechanism) is followed by a sudden rise of internal temperature (hyperpyrexia) which may quickly attain a point incompatible with life. This point varies with different animals, and with the same animal at different times. The condition of the blood was found to affect the animal's resistance to a marked degree, a state of anæmia greatly reducing its power of resistance. The experiments of Maurel[22] are also of interest as indicative of the cause of death in high elevation of temperature. He found that a temperature of 44° to 45° C. (111.3° to 113° F.) destroys the vitality of the leucocytes within a few minutes, a temperature of 43° to 44° C. (109.4° to 111.3° F.) within an hour, and from 42° to 43° C. (107.6° to 109.4° F.) within three hours. But if the temperature be reduced, the leucocytes regain their vitality.

Welch concludes, from his own observations and those of Naunyn, that a considerable part of the current arguments based upon experiments concerning the injurious effects of high temperature, must be revised. "Because an animal may be killed by raising its temperature to 111° F. (43.9° C.), or 113° F. (45° C.), it does not follow that an increase of temperature up to within 4° or 5° F. of this fatal point involves danger to life, or even any serious disturbance of the functions of the body. Although experiments in hot-air chambers show that in man brusque elevations of the temperature by only a few degrees give rise to serious symptoms, Krishaber[23] found that by habituation his temperature could be raised to 106.5° F. (41.4° C.), or 107.2° F. (41.8° C.) without much discomfort." From a clinical stand-point, therefore, much depends upon the gradual accession of the fever and the intervals of depression between the maximal points of elevation.

One of the earliest and most striking symptoms of fever is an increased rapidity of respiration, a symptom which has been generally attributed to the direct action of the high temperature upon the respiratory centres. Sihler[24] has, however, shown that another factor, and probably a more important one in experimental pyrexia, at least, enters into its production, namely, the stimulation of the skin. Although it is probable that the stimulation of the skin by heated blood may in a measure influence the rapidity of respiration in man, it undoubtedly does so to a much less degree than in the animal; and the truth still remains that increased respiration is due chiefly to the direct action of the warm blood upon the respiratory centres.

The heart is stimulated to increased action in pyrexia by the direct impression of the heated blood. Martin[25] has demonstrated that the heart beats quicker when supplied with warm blood than when supplied with cold blood, and that its rate of action depends much more upon the temperature of the blood in the coronary arteries than on that in the right auricle or ventricle. Although this fact has been demonstrated, we are not justified in supposing that the elevation of temperature is in a given case the only element in the production of the accelerated heart's action, for this may result in a great measure also from the action of the chemical irritants which are more or less directly the cause of the pyrexia.

Changes in the arterial tension and blood-pressure in fever have been attributed to the action of increased heat, but they are probably due, as Welch has shown, much less to increased temperature than to other causes, especially to the infectious agents which have induced the elevation of temperature.

Fatty degeneration of the heart, liver, kidneys, and other organs, and of some of the voluntary muscles, has been more or less generally observed as a consequence of continued high temperature; but there is not a unanimity of opinion as to how far these changes may be attributed to the elevation of temperature, and in how far they are the result of other causes. Heat is at least not the only element capable of producing the degeneration in these cases.

Many other phenomena, more or less generally attributed to the influence of high temperature, might be mentioned did space permit, and their importance justify. In many instances, however, the conclusions that would have to be drawn are more or less speculative in character. Among the phenomena referred to may be mentioned the almost universal wasting of tissues in fever, the reduction of digestive power, the constipation, the increased absorption of oxygen and increased discharge of carbonic acid to which reference has been made, the clouding of the intellect, the prostration, the coma-vigil, disturbances of tendon reflexes, muscular weakness and twitchings, and other manifestations of nervous disturbance. There can, however, be no doubt that in most of these instances the phenomena are attributable as much to the action of poisons circulating in the body as to the elevation of temperature. Flint[26] believes that while the special morbific cause of the disease in these cases is the cause of the delirium, etc., it is rational to suppose that it acts as a secondary cause of these phenomena, by virtue of changes induced directly by the prolonged elevation of body temperature. This statement is supported by the fact that the abstraction of heat, by means of cooling applications to the exterior of the body, is sufficient to arrest these nervous phenomena.

The leading premise from which certain writers have drawn their argument of the beneficial action of fever is the fact that the vitality of micro-organisms is destroyed by heat. Few of them can withstand a temperature of 40° C. (104° F.) except for a short time, the activity of their growth diminishing as the temperature approaches this limit. From this fact it is concluded that a moderate amount of fever is sanatory in its effects on the infectious diseases.

Treatment of Fever.—Fever being no longer regarded as of necessity an element of great danger, the

object of treatment is rather to exert a judicious control over it than to entirely overcome it. A reaction has set in against the too free administration of antipyretics, owing in great measure to the disappointment which has followed their universal adoption by the profession.

Liebermeister[27] has given us a judicious summary of the treatment of fever. He says that in many cases of febrile disease the height of the temperature constitutes a danger; that in these cases the therapeutic problem is to reduce the temperature. The basis of antipyretic treatment is the direct withdrawal of heat by means of cooling baths; yet in many cases the administration of antipyretic medicaments is at the same time necessary.

Flint's classification of the methods of treating fever is as follows:[26]

1. Reduction of the general temperature by the external application of cold.
2. Reduction of the temperature by the internal administration of antipyretics.
3. Promotion of general nutrition by alimentation.
4. Measures to supply to the system matters that can be consumed in the excessive production of heat, thereby retarding the destruction of tissues.

Directions for the reduction of temperature by means of the application of cold to the exterior of the body may be found in the REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, Vol. III., p. 69.

Treatment by the internal administration of antipyretics has not proved so successful as was anticipated a few years ago, upon the introduction of the synthetically prepared agents of the coal-tar series. Although these remedies as a class have the power to promptly and completely overcome fever, it has been found that they otherwise exert no beneficial action on the course or duration of the disease. In some instances, too, peculiar to the case no less than to the antipyretic agent employed, their administration has been followed by phenomena of exceedingly unpleasant or even alarming character.

No definite statements can be made as to the manner in which antipyretics reduce the temperature. Many experiments have been made for the solution of this problem, but the results have not been altogether satisfactory. Lauder Brunton is doubtless correct in classifying all antipyretics under the two heads of those which lessen the production of heat and those which increase the dissipation of heat. It is maintained by some writers, however, that these agents act largely by stimulating the thermotaxic mechanism.

Acetanilide, antipyrine, and phenacetine fairly represent the synthetically prepared antipyretics, and are probably more frequently prescribed than any other at the present time. Acetanilide is not only frequently administered alone, but is the active ingredient in nearly all so-called antipyretic compounds which have been introduced by manufacturing pharmacists of this country. Antipyrine, once the most popular of its class, has suffered much on account of unfavorable reports of its action. Gastric irritation, occasionally persistent vomiting and diarrhœa, a depressant action on the heart, syncope, are among the evil results attributed to it; but they are doubtless in great measure the result of its improper administration, particularly the giving of unnecessarily large doses. Phenacetine by many is esteemed as the safest of the antipyretics, and few instances of ill effects have been recorded.

For a thorough consideration of the subject of antipyretics, the reader is referred to works on materia medica, and to the articles in the present volume which treat of the individual drugs belonging to this class.

FIELD SURGEONS AND MEDICAL DEPARTMENTS, UNITED STATES ARMY. Since the publication of the REFERENCE HANDBOOK, in 1886, the United States has participated in no great wars. Its experience, however, in Indian hostilities has been constant, and certain knowledge regarding the duties and responsibilities of the Field Surgeon of the Army has thereby been increased and perfected.

With a medical staff into which are constantly received young men representing the highest education and culture, whose predecessors, now older, have possessed the same qualities, and in addition now possess the enthusiasm springing from success, and the knowledge born of experience, it is manifest that progress was to have been expected.

Accordingly I shall attempt to indicate such differences as have arisen in the past six years in the administration of the Medical Department in the United States Army, especially as to those duties and conditions treated of in the article on the duties of Field Surgeons which was published in Vol. III. of the REFERENCE HANDBOOK.

ORGANIZATION OF THE MEDICAL DEPARTMENT OF THE ARMY.—For the single Assistant Surgeon-General, the Chief Medical Purveyor, and four Surgeons, with the rank of colonel, existing in 1886, have been substituted by law, six Assistant Surgeon-Generals, with the rank of colonel.

Rank of medical officers.

Instead of the eight Surgeons and two Assistant Medical Purveyors, with the rank of lieutenant-colonel, have been substituted ten Deputy Surgeon-Generals, with the rank of lieutenant-colonel. In consequence, a Medical Purveying Department, separate and distinct, has been abolished.

Purveying Department abolished.

The motives influencing Congress to legislate for the above changes were principally two. The first was to assimilate the titles borne by the higher officers of the Medical Department to the titles borne by the higher officers of some of the other staff corps of the army. Thus in the Quartermaster and Pay Departments the colonels were styled, respectively, Assistant Quartermaster-General and Assistant Paymaster-General, and the lieutenant-colonels were Depnties. But, besides this, it had become manifest that the best work in purveying could be accomplished by allowing the Surgeon-General to select for purveying duties, from time to time, such men as had shown aptitude and taste for this special and peculiar business.

The men hitherto who, in natural sequence under the law, had become medical purveyors, were not necessarily those the best fitted for or the most desirous of discharging the duties of a purveyor, nor had they always been able or willing to give the bonds required of medical purveyors by law.

It had therefore been found necessary, for the reasons above stated and other reasons, to obtain the interference of the President of the United States, by whom alone medical purveyors could be assigned under the law to other duties than purveying. To obtain such interference when suddenly required was not always easy or convenient, and the Surgeon-General therefore found it

necessary to recommend legislation on the subject. In future the most suitable medical officer will be selected and detailed as medical purveyor.

Number of medical officers.

The number of surgeons, with the rank of major, 50, remains unaltered; also the number of assistant surgeons, viz., 125; of whom those under five years in service have the rank of first lieutenant, and those of more than five years' service the rank of captain.

The full number allowed are not, however, actually in the service; that is, the casualties have been more numerous than the successful candidates who have passed the examination before the Medical Board, so that at the present writing there are thirteen vacancies among the assistant-surgeons. A less number, however, are on leave of absence than when the REFERENCE HANDBOOK, Vol. III., was published.

The strength of the army is unchanged, the last Army Register showing an aggregate strength of 28,526, so that the proportion of medical officers to the whole army is unchanged in the last six years. Certain changes in the army, however, have rendered medical administration somewhat easier.

The number of military posts has been sensibly diminished by the concentration of troops. Consequently it has been found possible, with the same number of medical officers in the army, to supply a greater number of military posts with more than one medical officer, and in consequence the additional medical officer has been found available to accompany detachments or larger commands for field service, when formerly the commands would have been obliged to proceed without a medical officer, and to have sent their sick and wounded to the nearest military post for treatment. Manifestly this course was only possible when, in consequence of operating in its own country, as the United States army has done, the moving troops were sufficiently near to military posts to send there the sick and wounded without too much inconvenience and suffering.

Regimental medical officers in the National Guard.

During the past eight years the National Guard of the different States have assembled at different and suitable places as camps for purposes of discipline and inspection. The surgeons and assistant surgeons have accompanied the various military organizations to these camps, but not always in the full numbers authorized by law. The most of these camps have been inspected by duly authorized inspectors; and without attempting to give the reports of all these inspectors (the great majority of which I have not seen) as to the medical organization and its fitness to bear the strain of a campaign, I may say that while none has been perfect, none has been found absolutely unfit for its work, and most have merited praise, while the medical officers have been of more than ordinary intelligence.

The allowance of medical officers to each regiment has been one surgeon and two assistant surgeons with the same rank as in the regular army.

Proper proportion of medical officers to army.

The experience of the past six years does not change our conclusion that the size of the medical corps of the United States army is not too large or too small in proportion to the size of the army; and that the most proper number of medical officers to a regiment of the strength now authorized by law, where the medical officers also are regimental, is one surgeon and two assistant surgeons.

A new law passed by the last Congress requires that assistant surgeons shall pass an examination before promotion to the grade of captain; this in addition to the examination required by former laws.

Qualifications and disqualifications for becoming soldiers.

RECRUITS.—Inasmuch as the necessity for soldiers is greater in time of war than in time of peace, the physical examination of recruits becomes more lax in the former period, and so it happens that in the army of the United States physical examinations have been more strict for soldiers, cadets, and officers in recent years. In regard to the examinations, the directions which appeared at the bottom of column first, page 106, Vol. III., of the REFERENCE HANDBOOK, are no longer issued, and the rules and entire system of examination have been arranged for the better.

So late as at the beginning of 1892, the adjutant-general of the army issued a memorandum of instructions practically forbidding the enlistment, save as musicians, of any persons under twenty-one years of age.

These instructions are in entire harmony with the views expressed, concerning the minimum age of enlistment, on page 106, Vol. III., of the HANDBOOK.

Intellectual and moral examination.

In the effort to raise the standard of examination, the present system gives much attention also to the *intellectual* and *moral*. On these subjects the Epitome (which is the standard of instructions for the army) uses the following language: "*Intellectually*, although no educational standard officially is established, a soldier should be able to read and write, and should also be quick and clear in his understanding. The advance in the science and art of war and the improvement in modern fire-arms call for a higher degree of intelligence than was required of the soldier in the past. This is recognized by the Government by establishment of schools and libraries, by providing reading-rooms that are liberally supplied with periodicals and newspapers, and by opening the way for promotion to all who avail themselves of these opportunities for advancement. The care and attention that the soldier is required to give to his weapon and ammunition, the drill which its use entails, and the skill which may be attained by the practice of rifle-firing develop individuality, excite interest and ambition, and tend to make the profession attractive. It is therefore desirable that men should be selected who can appreciate this life and who have the mental capacity to profit by it. The *moral* character should be scrutinized with care in order that enlistments from the vagrant and criminal classes may be avoided. The recruiting rendezvous is a favorite haunt for these men, and a study of their personal characteristics will well repay the recruiting officer for his labor. The vagrant seeks admission to the army, usually at the beginning of winter, for shelter, food, and clothing, without any intention of completing his enlistment or of performing any more service than he is compelled to perform. The criminal seeks to bury his unsavory history under an assumed name, and, by service in distant stations, to escape the observation of those who know him. The evil influence in a company of even one of this class cannot be over-estimated, and no degree of physical perfection or soldierly bearing should induce a recruiting officer to accept his service. Happily, as a rule, the evidence of a life of debauchery is so plainly marked in the features and in the person that an ordinary observer is able to estimate the true character of such an applicant without difficulty."

This is almost an ideal picture, and it is to be desired that the candidates for enlistment may all be scholars and Christian gentlemen. But it has been found in the past that the degree of education and virtue is not always to be discovered and measured by the appearance of the subject, and both uneducated criminals and vagrants are often able to elude the examination of surgeon and recruiting officer combined.

Further remarks concerning the physical examination of recruits will be here omitted, as it is understood that the subject will be fully treated elsewhere in this volume.

STANDARD SUPPLY TABLE OF THE MEDICAL DEPARTMENT, UNITED STATES ARMY.—In the course of the past six years, from time to time as occasion demanded, various articles have been added to the army list of medical supplies and various articles dropped therefrom.

Various officers contributed their views on what was needed and not needed, for the medical supplies of the army in field and garrison, and finally a Board was ordered to convene in New York City for the purpose (among others) of revising the Standard Supply Table of the Army Medical Department.

The result of all the consideration of the subject has

Field Surgeons.

been that the following articles have been dropped from the Supply Table, page 108, Vol. III., REFERENCE HANDBOOK.

ARTICLES DROPPED FROM OLD SUPPLY TABLE.

Medicines.

Acacia (Gum Arabic).
Iron, solution of tersulphate.
Morphine, acetate of.
Oil, olive.
Pepsin, lactated.
Pills, mercury, green iodide of.
Potassium bichromate.
Acid hydrobromic.
Arsenic and mercury, solution of iodide of.
Brayera.
Bromine.
Cinchona, pulv.
Codeine.
Extract castanea, fluid.
Extract eucalyptus, fluid.
Extract glycyrrhiza, fluid.
Extract Indian cannabis.
Extract pilocarpus (jaborandi).
Extract physostigma (calabar bean).
Extract taraxacum, fluid.
Mercury, metallic.
Oil of lemon.
Oil of rosemary.
Pills, arsenic.
Pills, arsenic, iodide of.
Potassium, cyanide of.
Potassium, nitrate.
Strychnine, sulphate
Tar (wood).
Tincture cimicifuga.
Tincture sanguinaria.
Tincture serpentaria.
Wax, white.
Zinc, solution of chloride of.
Zinc, oleate.

Hospital Stores.

Arrow-root.
Chocolate.
Cinnamon.
Corn starch.
Farina.
Gelatine.
Ginger.
Meat-juice, Valentine's.
Nutmeg.
Pepper, black.
Pepper, cayenne.
Tapioca.
Tea.
Wine.

Instruments, Expendable.

Nipple-shields.

Dressings.

Antiseptic dressings for use with spray apparatus.
Cotton wadding.
Splints in sets.
Stenta book.

Stationery.

Blocks, memorandum.
Sealing-wax.

Miscellaneous, Expendable.

Mugs, delft.
Spoons, medicine, delft.

Instruments, Non-expendable.

Atomizer, steam.
Meteorological instruments.
Ophthalmoscope.
Speculum for ear.

Clothing and Bedding.

Bedsacks.
Blankets, gray.
Blanket cases.
Counterpanes, striped.
Mattresses, felt.
Pillow-cases, linen.
Pillow-ticks.
Sheets, linen.
Drawers.
Gowns, dressing.
Socks, woollen.

Miscellaneous, Non-expendable.

Bed-pans, metal.
Bed-ticket, frames.
Clothes-pins.
Clothes-wringers.
Hatchets.
Medical saddle-bags.
Medicine-cases.
Medicine-panniers.
Medicine-wagons.
Pails, chamber.
Pitcher, britannia.
Sad-irons.
Saw, wood.
Washboards.

This list of articles dropped is not as extensive as the list of articles which have been added to the old Supply Table and which follows.

In a certain number of cases a certain preparation of medicine is dropped from the old table, and a different preparation of the same medicine appears in the list of articles added, so that it is merely a case of a substitution.

ARTICLES ADDED TO SUPPLY TABLE.

Some of the articles above named were habitually issued prior to this, but their issue being authorized since the former Supply Table, or never having been formally authorized at all, their names now appear for the first time in a Supply Table.

In looking over the names of the new medicines added to the list it will be noticed that a portion are:

1. New remedies, whose properties have been made public since the former Supply Table was published.

2. A certain portion are alkaloids and concentrated principles, a little of which goes a long way.

3. A very large portion, almost one-half, or twenty-seven out of sixty-four, are in the form of tablets or disks, convenient like Class 2 for transportation and use in the field. And

4. (It may seem a little strange), but a portion of the articles are the same as those which have been dropped from a Supply Table anterior to that published in this HANDBOOK.

This latter fact simply shows a change of fashion in medication, as well as the difficulty, and even impossibility, of any one man, or set of men, legislating or making rules that will be satisfactory and convincing to all others, or that should not be changed as time progresses. No differentiation has yet taken place of a Supply Table merely for the field, although, in all probability, ere many months one will be made out by competent authority. In the meantime, the surgeon must select from the table for field service such articles of medicine as may commend themselves to his taste, his experience, and his judgment.

Selection of medicines for field service.

For field service the Supply Table is largely redundant, and in selecting what he will take into the field—where transportation is scarce and hard to obtain—the surgeon must discriminate wisely, taking what he will need and use the most,—what is most concentrated and easy of transportation.

The same principle must guide him in the selection of his instruments and other surgical supplies, and he must bear constantly in mind that, after a battle, the wounded will ordinarily be cared for not by the regimental surgeon, but by other surgeons detailed for that purpose; and that ordinarily the cases of sickness, serious and of long duration, will be treated elsewhere than at the regiment.

Selection of instruments for field service.

The experience of the medical director will also come to the aid of the field surgeon, as by the first-named officer requisitions of regimental surgeons will be modified before they are sent to the medical supply depôt for issue; and it is the business of this officer to see that surplus supplies are at the depôt, to make good unexpected and unusual losses and deficiencies, by capture or otherwise.

By the regulations governing the issue of medical supplies heretofore, the fact that different medical officers might differ in their choice of medicines was more than recognized. In the first place, it was officially stated that a supplementary list of drugs and medicines had been published, to "permit the indulgence of individual preferences." In the second place, it was officially announced that "requisitions for articles not on the Supply Table, and which have been approved of as of value in the treatment and care of the sick, will be favorably considered by the Surgeon-General when the amount of appropriation for medical and hospital supplies will warrant."

The gratification of individual preferences has not been so fully provided for in the new Supply Table; but in view of the progressive and far-seeing policy which has characterized the official doings and utterances of the medical bureau for the past thirty years, it can hardly be believed that a liberal spirit will not guide it in its action in the future, regarding the issue of articles not in the Supply Table. Certainly all tools are not equally fit for the same purpose, and equally truly different men use with differing skill the same tool and different tools.

Property Accountability.—Medical officers receiving and receipting for medical and hospital property are held strictly accountable therefor, and should fully acquaint themselves with the regulations on the subject. In consequence of their failure to obtain this knowledge, or their neglect, for any reason, to comply with those regulations, it has happened very frequently that young or inexperienced medical officers of the regular army, the volunteer forces, or the militia have found (and hereafter are in grave danger of finding) themselves confronted with considerable pecuniary losses, to meet which their pay is stopped. Medical property is not difficult to account for if properly cared for. It is divided into expendable and non-expendable, and in reference to the latter the greatest losses to the medical officer occur, but are unnecessary.

Property non-expendable must be either accounted for by the receipt of some one else, or, if worn out, broken, or destroyed, evidence of such fact must be presented to the proper person, sometimes called an inspector, sometimes a board of survey, sometimes the accounting officer, who receives the returns of property, which have elsewhere been named as required of officers accountable for property.

Remembering these simple facts, medical officers will see the necessity of familiarizing themselves with the regulations on the subject, which can easily be complied with, and thus will save themselves the annoyance of pecuniary loss.

In one special case the military surgeon may destroy property in his discretion, for the regulations of the Supply Table provide that tents, clothing, hospital furniture, and other articles used in the treatment of contagious diseases, will be disinfected or burned under the supervision of a medical officer; and the articles destroyed to prevent contagion must be accounted for by a certificate of the officer responsible, setting forth fully the circumstances necessitating such destruction.

"The medical officer has discretionary powers, which are based on his knowledge of specific contagions and methods of disinfection. The efficiency of many of these methods is now so well established that they supersede the necessity for burning."

Since the publication of the Supply Table in Vol. III., the medical department has assumed the charge of supplying disinfectants for general post sanitation, and directs post surgeons as follows:

"(*a*) Chloride of lime should be used only as a disinfectant, properly so called, the cheaper sulphate of iron being used as an antiseptic and deodorant in privies, slop-barrels, etc. When a jar of chloride of lime has been opened, and a part of the contents removed, it should be sealed again with plaster of Paris. Solution of chlorinated soda will be issued in small amounts only for special personal disinfection.

"(*b*) The selection and use of proper disinfectants and deodorants will be determined by the senior medical officer, who should not issue them unless, in his opinion, their use is necessary and proper. He will give explicit instructions as to the quantities to be used, strength of solutions," etc.

Sterilized dressings, etc., will be supplied in small quantities only for post use. Their preparation is so simple and so well understood that they should be prepared as needed.

Meteorological instruments will not, in future, according to the new Supply Table, be issued by the medical department. When required for use at designated posts, they will be obtained by application direct to the Chief of the Weather Bureau, Department of Agriculture.

As will appear further on, meteorological reports by medical officers are discontinued. It is not clear that this new rule is wise, and many medical officers will regret that they are deprived of their meteorological instruments.

In this country the army surgeon has been the pioneer in weather observations, which, for many years, have been taken by them at every military post and forwarded to the War Department when, of other observers, there were none on the unsettled frontier. The familiarity with hygrometric and temperature conditions thus acquired by the military surgeon accustomed him to see relations and connections between these conditions and certain coincident pathological conditions, and often much to the advantage of the patient and the community—an advantage not precisely to be defined sometimes, and therefore properly to be called immeasurable.

It is not to be denied that, for the community at large, the meteorological observations regularly taken by the skilled observers of the Agricultural Bureau will take the place of those formerly taken by the military surgeon. Still, it would seem that it might be to the advantage of all concerned, were medical officers to continue to make such observations regularly at their hospitals.

No list of medical books for issue is included in the present Supply Table, and the reason given therefor is that, owing to the rapid advances in medicine, a large part of any fixed literature soon becomes obsolete. To a certain extent this is true, but the truth is only on the surface. The Table further provides that such new books as may be selected by the Surgeon-General will be furnished without requisition, and nothing is said concerning the issue of any other books than those so selected.

This provision seems also unwise. In the first place, there are a certain proportion of books on medicine and surgery published that are standard, and that every medical man feels the need of, and this independently of their selection by any one man. In the second place, a large number of medical men have well-defined and considered preferenees for certain authors and certain books. Of these books none other will take the place, and it is hard to see why these preferences should be ignored, or how any Surgeon-General or other man could know them.

It is to be hoped that ere long this regulation may be changed, and a list of such books be published for issue as will meet the general consensus of the military surgeons, for whose study and information the books are issued.

It is important that the military surgeon of the National Guard and Militia, as well as of the Regular Army, should know precisely what tools will be presented to him to do his work with, both in field and garrison.

The new Supply Table divides the supplies under the following headings:

1. Medicines, expendable.
2. Disinfectants, expendable.
3. Hospital stores, expendable.
4. Surgical instruments and appliances, not expendable.
5. Surgical dressings, etc., expendable.
6. Stationery, expendable.
7. Bedding, clothing, etc., not expendable.
8. Furniture, not expendable.
9. Dispensary accessories, not expendable.
10. Kitchen and mess utensils, not expendable.
11. Miscellaneous, not expendable.
12. Miscellaneous, expendable.

Some notice is now required of some of those articles included in Class 4.

1. Dispensing set (bottles and jars).
2. Apparatus, spray-producing, (for petrolatum).
3. Case, aspirating.
4. " capital operating, No. 1.
5. " capital operating, No. 2.
6. " eye and ear.
7. " field operating.
8. " genito-urethral.
9. " urethal.
10. " minor operating.
11. " obstetrical and gynecological.
12. " pocket personal.
13. " post-mortem.
14. " dissecting.
15. " stomach-pump.
16. " tooth-extracting.
17. Inhaler and vaporizer.
18. Microscope and accessories.
19. Surgical pump.
20. Syringe, hypodermic.
21. Thermo-cautery, Paquelin's.
22. Type-writer.
23. Vision-test set.
24. Amputating case.
25. Exsecting case.
26. General operating case.
27. Trephining case.
28. Chemical set with measuring apparatus.
29. Tool-chest.
30. Commode chest (No. 3).
31. Pack-saddle for medical and surgical chests.
32. Folding field furniture.

No. 1. The dispensing set consists of a suitable and sufficient number of bottles and jars.

Nos. 4 and 5. The contents of these cases vary but little from each other.

No. 6 contains all that is needed, save by the advanced specialist, for ordinary eye and ear surgery.

Nos. 8 and 9. The latter does not differ much from the genito-urinary case, whose contents are given farther on. The large-sized sounds in the genito-urinary case make it preferable to either 8 or 9 in certain cases where urethral dilatation is required.

Nos. 13 and 14. The issue of No. 14 will cease when those now on hand are exhausted, as No. 13 can fully supply its place.

No. 18. The Medical Department have issued the "Universal" and the "Investigator"—two different patterns of mieroscopes—manufactured by the Bausch & Lomb Optical Company. Beck's Popular Binocular, also, has been issued to a limited number.

No. 28. This is supplied only in special cases where analytic and other chemical work is to be prosecuted.

No. 29 is a small set of carpenter's tools.

No. 32 comprises a few articles, such as folding chairs and tables, that may be easily packed and carried in the field.

Concerning the other articles in the above list it seems unnecessary to say more than that they do not materially differ from other similar cases and instruments with which every surgeon is familiar.

In regard to the list of cases, etc., which follows, it seems necessary to name the contents, either because they differ from the ordinary cases of the same name, or because they possess peculiarities due to their preparation for use in the military service.

1. Apparatus, compressed air.
2. " restraint.
3. Case, dental.
4. " emergency.
5. " field.
6. " forceps, hæmostatic.
7. " genito-urinary.
8. " pocket, aseptic.
9. " " post.
10. " of trial lenses.
11. Pouch, hospital corps.
12. Pouch, orderly.
13. Bacteriological set.
14. Medical chest, U. S. Army, No. 1.
15. Surgical chest, U. S. Army, No. 2.
16. Field-desk, No. 4.
17. Mess-chest, No. 5.
18. Food-chest, No. 6.
19. Reserve-chest, No. 7.
20. Ice machine.
21. Articles issued by the Quartermaster's Department.
22. Articles issued by the Ordnance Department.

Contents of foregoing:

Apparatus, Compressed Air.

Air-container, with gauge, number	1	Davidson's sprays, in set, viz:	
Force-pump, number	1	Atomizer-tubes, h. r., number	3
Tubing, thick rubber, silk covered, connecting container with cut-off, *exp.*, feet	8	Bottles with h. r. caps, number	3
Tubing, thick rubber, connecting container with force-pump, *exp.*, feet	4	Cut-off, metal, number	1
		Stand for bottles, number	1
		Tube connector, h. r., *exp.*, number	1
		Tube wires for cleaning, *exp.*	2

Apparatus, Restraint.

Anklets, pair	1	Strap, bed, as per circular, number	1
Keys to lock buckles, number	5	Strap, waist, number	1
Muff, leather, number	1	Wristlets, pair	1
In wooden box, with handle and lock.			

Case, Dental.

Burnishers (Nos. 3, 29, 36), number	3	Gutta-percha, *exp.*, ounce	1
Chisels (Nos. 77, 135), number	2	Handles for instruments, number	6
Explorer (No. 5), number	1	Hone, number	1
Excavators (Nos. 10, 14. 16, 21, 41, 82, 86, 141, 143, 145), number	10	Mirror, number	1
		Paper, bibulous. *exp.*, sheets	6
		Scaler (No. 3), number	1
Files (2 each of Nos. 00, 0, 1) number	6	Spatula (No. 1), number	1
Forceps, college, number	1		

In small morocco case.

Case, Emergency.

Tablets in half-ounce bottles:		Potassium bromide, gr.	10
Acetanilide, gr.	3	Potassium chlorate, gr.	5
Acid boracic, gr.	5	Quinine sulphate, gr.	3
Acid tannic, gr.	5	Sodium salicylate, gr.	5
Alum, gr.	5	Sulphonal, gr.	5
Ammonium chloride, gr.	5	Tincture aconite root, m.	2
Antipyrine, gr.	5	Tincture digitalis, m.	5
Calomel, gr.	2	Tablets, hypodermic, in tubes.	
Camphor, gr. 2, and opium, gr. 1	*	Apomorphine hydrochlorate,* gr.	1/10
Cathartic compound	*	Atropine sulphate, gr.	1/100
Colchicum, fluid extract, m.	1/2	Cocaine hydrochlorate, gr.	1/6
Cough	*	Digitaline, gr.	1/100
Diarrhœa	*	Ergotine,* gr.	1/10
Dover's powder, gr.	5	Morphine sulphate,* gr.	1/4
Ergotine, gr.	2	} Morphine sulphate,* gr.	1/8
Ipecac, gr.	1	} Atropine sulphate,*	1/100
Morphine sulphate, gr.	1/8	Pilocarpine hydrochlorate, gr.	1/6
Nitro-glycerine, gr.	1/100	Quinine bimuriate, gr.	1/2
Opium, gr.	1	Strychnine sulphate, gr.	1/60
Phenacetine, gr.	5		
Syringe, hypodermic, not expendable, number			1
Thermometer, clinical. (See par. 44), number			1

* Tablets marked thus are in the hypodermic syringe case.

Case, Field.†

Bistoury, curved, number	1	Ligature silk, *exp.*, cards	2
Catheter, silver, jointed, number	1	Needles, surgeon's, *exp.*, number	12
Director and aneurism needle, number	1	Probe (Nélaton's), number	1
Forceps, artery and needle, combined, number	1	Saw-blade, movable back, number	1
Forceps, bone, number	1	Saw-blade, handle, number	1
Forceps, bullet, number	1	Scalpel, number	1
Forceps, dressing, number	1	Scissors, straight, number	1
Knife, amputating, blade, number	1	Serre-fines (Langenbeck's), number	4
Knife, amputating, handle, number	1	Tenaculum, number	1
		Wax, *exp.*, piece	1
		Wire suture, silver, *exp.*, loops	3

In wooden case, with leather pouch and sling strap, with buckle and snap hooks.

† This is the case recently issued as "surgeon's field case."

Case, Forceps, Hæmostatic.

Halsted's straight, number	1	Little's fenestrated, number	1
Halsted's curved, number	1	Tait's long grip, number	1
Jones's angular, number	1	Tait's short grip, number	1
Jones's straight, number	1	Thornton's T, number	1
		Wood's [Pean's] large, number	2
		Wood's [Pean's] small, number	2

In morocco case.

Case, Genito-Urinary.

Bistoury for meatus (Otis's), number	1	Urethrometer (Otis's), hinged, number	1
Bougies à boule (Otis's), metal, nickel-plated, Nos. 8 to 40, inclusive, number	33	Urethrometer, rubber covers for, *exp.*, number	12
Endoscopes (Otis's, h. r.), Nos. 22, 26, and 32, number	3	Urethrotome, Maisonneuve's No. 8 (Otis's) gauge, with two blades, two filiform bougies and one extra tunnelled tip for whalebone guide, number	1
Gauge (Otis's) steel, number	1		
Guides (Otis's), whalebone, number	2	Urethrotome, dilating (Otis's), straight, with two blades, number	1
Sounds (Otis's), short beaked, steel, nickel-plated, Nos. 20 to 40, inclusive, number	21		

In mahogany case.

Case, Pocket, Aseptic.

Bistoury, curved, number	1	Needle, aneurism, number	1
Bistoury, curved, probe-pointed, number	1	Needle, aneurism, and grooved director, number	1
Bistoury, straight, number	1	Needle, exploring, number	1
Catheter, jointed, male and female tips, number	1	Needles, surgeon's, *exp.*, number	12
Caustic holder, number	1	Probe (Nélaton's), number	1
Forceps, needle and fenestrated, artery, number	1	Probe, silver, number	1
Forceps, long-jawed, number	1	Scalpel, number	1
Lancet, thumb, number	1	Scissors, number	1
Ligature silk, *exp.*, card	1	Tenaculum, number	1
		Tenotome, number	1
		Wax, *exp.*, piece	1
		Wire suture, silver, *exp.*, loops	3

In leather case, with metal clips and chamois cover.

Case, Pocket, Post.

This name will be used when reference is made to the red morocco pocket-case with chamois cover issued during the past few years for post use.

The list of contents is the same as that of the aseptic pocket-case, but the aneurism and exploring needles, knives, and tenaculum are detachable from the two hard-rubber or ivory handles. Some cases contain a combined needle and fenestrated artery forceps and a hæmostatic forceps; others a plain artery and a dressing forceps.

Case of Trial Lenses.

Bausch & Lomb.

Twenty pairs spherical convex lenses.
Twenty pairs spherical concave lenses, both from 2 to 160 English inches focus (D. 20–0.25).
Eleven cylindrical convex lenses.
Eleven cylindrical concave lenses, both from 8.888 to 160 English inches focus (D. 4.50–0.25).
Six prisms, 2°, 3°, 4°, 5°, 8°, 12°.
Five disks, one white and one ground glass, one plain metal, one metal with hole in centre, and one metal with stenopaic slit.
Four colored glasses—red, blue, green, and brown.
One graduated trial frame, No. 3, double cell.
One graduated trial frame, No. 2 (double cell, adjustable).
In mahogany case, with lock and two keys.

Queen.

Twenty pairs spherical convex lenses.
Twenty pairs spherical concave lenses, both from 2 to 48 inches focus.
Eight cylindrical convex lenses.
Eight cylindrical concave lenses, both from 9 to 72 inches focus.
Five prisms, 2°, 3°, 4°, 5°, 8°.
Three metal disks, one plain, one with hole in centre, and one with stenopaic slit.
Four colored glasses—red, blue, green, and brown.
One single lens-holder.
One trial frame.
In mahogany case, with lock and key.

Pouch, Hospital Corps.

Ammonia, aromatic spirits, *exp.*, oz	1	Petrolatum, carbolized, *exp.*, oz	½
Bandages, roller, *exp.*, number	4	Pins, common, *exp.*,* paper	1
Candle, in tin box, *exp.*, number	1	Pins, safety, *exp.*,* number	6
First-aid packet, *exp.*, number	1	Plaster, adhesive, *exp.*, spool	1
Forceps, dressing,* number	1	Scissors, medium,* number	1

Glass, medicine, *exp.*, number	1	Lint, sublimated, *exp.*, oz	2
Petrolatum, carbolized, *exp.*, oz	½	Wool, boracic, *exp.*, oz	2

* The six half-ounce bottles in this case contains the following tablets:

Acetanilide, gr.	3	Cough	
Antiseptic		Diarrhœa	
Compound cathartic		Quinine, gr.	3

Bacteriological Set.

The following articles constitute the Bacteriological Set, which will be issued in special cases:

Apparatus:		Apparatus:	
Apparatus, filling, and stand, number	1	Flasks, graduated, with lip, 1,000 c.c., number	4
Bath, water, copper, number	1	Incubator, lead-lined, 40 × 25 × 25, number	1
Bath, tripod for, number	1	Micro-burner, 1 flame, number	1
Burner (Koch's) number	1	Paper, filtering, *exp.*, q	1
Burner and regulator (Bunsen), number	1	Paper, filtering (Swedish), *exp.*, q	1
Burner, stand for, number	1	Pipettes, 1 c.c., number	4
Dishes, double (Petri's), number	12	Pipettes, 2 c.c., number	4
Filters (Pasteur), mounted in flask, number	2	Pipettes, 5 c.c., number	4
Flasks (Erlenmeyer's), 8 oz., number	12	Pipettes, 10 c.c., number	2
Flasks, graduated, 500 c.c., number	4	Platinum wire, fine, 4-inch, pieces	3
		Platinum wire, medium, 4-inch, pieces	3

Bacteriological Set.—(Continued.)

Apparatus :	
Platinum wire, heavy, 4-inch, pieces	3
Regulator, gas (Reichert's), number	1
Rods, glass, ⅛-inch, *exp.*, lb.	⅛
Sterilizer, hot-air, 23 × 30 × 20, number	1
Sterilizer, steam (Arnold's) number	1
Stoppers, solid rubber, assorted, *exp.*, lb	⅛
Syringe, sterilizable (Koch's), 1 c.c., number	1
Test measures, footed, 5 c.c. number	1
Test measures, footed, 10 c.c., number	1
Test measures, footed, 100 c.c., number	1
Test measures, footed, 500, c.c, number	1
Test tubes, bath for, 1 × 6 inches, copper, with extra cover, number	1
Test tubes, thin glass, 6 × ¾ inch bore, *exp.*, number	300
Thermometer, 0–50° C., number	1
Thermometer, 0–200° C., number	1
Apparatus :	
Tubing, glass, ⅛, 3/16, ¼-inch bore, *exp.*, lbs	3
Tubing, rubber, *exp.*, ft.	12
Culture media and staining reagents :	
Agar-agar, lbs	2
Aniline oil, pure, lb	1
Bismarck brown, oz	1
Carmine, best, oz	1
Eosine, oz	½
Fuchsine, oz	1
Gelatine, best, lbs	2
Glycerine, c. p., lb.	1
Hæmatoxylon, dr.	2
Methyline blue, oz	1
Peptone (Wittles's), lb	½
Saffranine, oz	1
Zylol, pure, lb. (These are expendable.)	1
Bacteriological Technology (Salomonsen), copy	1
Bakteriologische Diagnostik (Eisenberg), copy	1
Die Mikroorganismen (Flügge), copy	1
Objective, oil immersion, 1/12 or 1/15 inch, number	1
Nose-piece, double or triple, number	1
Condenser (Abbe), number)	1

Medical Chest, U. S. Army, No. 1.

The contents of the medical and surgical chests are expendable with the exception of those to which an asterisk is prefixed.

Contents of Tray.

Left of tray—4-oz. bottles :	
Acetanilide, tablets, gr.	3
Camphor and opium, tablets	..
Cathartic compound, tablets	..
Cathartic compound, veg., tablets	
Copaiba compound, tablets	..
Cough, tablets	
Diarrhœa, tablets	..
Dover's powder, tablets, gr.	5
Liniment, tablets, gr.	20
Potassium bromide, tablets, gr.	10
Quinine sulphate, tablets, gr.	3
Sodium bicarbonate, tablets, gr	5
Sodium salicylate, tablets, gr.	5
Magnesium sulphate, oz. (And two empty bottles.)	4
Back of tray—8 and 16 oz. bottles :	
Alcohol, oz	16
Ammonia, stronger water, oz.	8
Brandy, oz.	16
Chloroform, oz.	8
Ether, oz.	16
Oil, castor, oz	8
Turpentine, oz.	8
Whiskey, oz.	16
Stoppers, rubber, for above, number	10
Centre of tray :	
Cotton-wool	q.s.
Envelopes, small, for tablets, number	100
Graduates, glass, 2-oz., number	1
Graduates, glass, minim, number	1
Labels for vials, number	50
*Links, split, for pack saddle, number	4
Ointment boxes, in nests of three, nests	4
*Pocket stove, number	1
Vials, 2-oz., number	10
Front of tray—½-oz. bottles:	
Acid, arsenious, tablets, gr.	1/40
Alterative, tablets	..
Capsicum, tablets, gr.	½
Colchicum, fl. ext., tablets, m.	½
Croton-oil, tablets, m.	1/10
Ergotine, tablets, gr.	2
Iodine, oz.	½
Nitro-glycerine, tablets, gr.	1/100
Podophyllin, tablets, gr.	¼
Santonin, tablets, gr.	¼
Silver nitrate, fused, oz.	½
Tr. digitalis, tablets, m.	5
Tonic, tablets	
Right of tray—2-oz. bottles :	
Acid boracic, tablets, gr	5
Acid tannic, tablets, gr	5
Alum, tablets, gr.	5
Ammonium chloride, tablets, gr.	5
Antipyrin, tablets, gr.	5
Bismuth subnitrate, tablets, gr	5
Blue mass, tablets, gr.	5
Calomel, tablets, gr.	2
Chloral, tablets, gr.	5
Ipecac, tablets, gr.	1
Lead acetate, tablets, gr.	3
Morphine sulphate, tablets, gr.	1/8
Opium, tablets, gr.	1
Peptic, tablets	..
Phenacetine, tablets, gr.	5
Potassium chlorate, tablets, gr.	5
Potassium iodide, tablets, gr.	5
Salol, tablets, gr	5
Tr. aconite root, tablets, m.	2
Zinc sulphate, tablets, gr.	5

Contents of Drawers.

Drawer No. 1.	
Hypodermic tablets : †	
Apomorphine hydrochlorate, gr. 1/10, bott.	1
Atropine sulphate, gr. 1/100, bott.	1
Cocaine hydrochlorate, gr. 1/6, bott.	1
Ergotine, gr. 1/10, bott.	1
Morphine sulphate, gr. 1/8, bott	1
Pilocarpine hydrochlorate, gr. 1/8, bott.	1
Qainine bimuriate, gr. 1/2, bott	1
Strychnine sulphate, gr. 1/60, bott.	1
Ophthalmic disks:	
Atropine sulphate, gr. 1/500, 50 in box, box	1
Eserine sulphate, gr. 1/2000, 50 in box, box	1
Miscellaneous :	
*Caustic holder, rubber, number	1
*Corkscrew, folding, number	1
Medicine-droppers, number.	2
*Pencil, indelible, number	1
Pencil, indelible, leads for, number	6
Pencils, camel's-hair, number	12

Medical Chest, U. S. Army, No. 1.—(Continued.)

Contents of Drawers.—(*Continued.*)

Drawer No. 1.—(*Continued.*)	
Miscellaneous :	
*Syringe, hypodermic, number.	1
Thermometer, clinical, number	1
*Tongue-depressor, number	1
Drawer No. 2.	
Bandages, suspensory, number	5
Flannel, red, yds.	1
Jute, salicylated, in 1/4-lb. pkgs., pkgs.	4
*Syringe, rubber, self-injecting, number	1
Drawer No. 3.	
Book, prescription, number	1
*Forceps, dressing,‡ number.	1
*Index of Medicine (Carpenter), copy	1
Plaster, blistering, yd.	1
Plaster, mustard, yds.	4
*Reagent case, § number.	1
*Scissors, number	1
*Spatula, number	1
Spoon, tea, number	1
*Stethoscope, h. r., number	1

Syringes, p. g., in wooden case, number	3
Syringes, p., h. r., number	5
Tags, diagnosis, 24 in book, book	1
*Towels, number	2
Drawer No. 4.	
Beef extract, in 4-oz. cans, lb.	1
Jute, salicylated, 1/4-lb. pkgs., pkgs.	6
Drawer No. 5.	
Bandages, roller, assorted, number.	30
Cotton, absorbent, 1/4-lb. pkgs., pkgs	4
Soap, castile, oz.	8
Drawer No. 6.	
Candles, number	18
Flaxseed meal, lbs.	2
Drawer No. 7.	
*Cupping tins, number	4
Gauze, sublimated, 1-yd. pkgs., pkgs	3
Lint, absorbent, 1/4-lb. pkgs., pkgs.	4
*Scarificator, number	1

With list of contents stamped on morocco pad which is carried, reversed, under the cover of chest.

† The contents of tubes of hypodermic tablets hereafter issued to replace those expended should be placed in the screw-cap bottles.

‡ For the convenient removal of cotton from tablet bottles.

§ Consisting of 1 tube citric acid ; 1 medicine-dropper : blue litmus paper ; 1 tube potassium ferrocyanide ; 1 tube sugar-test powder ; 1 test tube ; *1 urinometer. With circular of directions.

Surgical Chest, U. S. Army, No. 2.

Contents of Tray.

4-oz. Bottles :	
Acid boracic, tablets, gr. 5, bott	1
Antiseptic tablets, botts.	2
Compound cathartic tablets, bott	1
Opium, tablets, gr. 1, bott.	1
Potassium bromide tablets, gr. 10, bott	1
*Bucket, folding, canvas, number	1
*Catheters, flexible, number	1
Dressing paper, roll	1
Ether, lb.	1
Felt for splints, pieces	2
*Links, split, for pack saddle number	4
Muslin, yds.	3
8-oz. Bottles :	
Carbolic acid, pure, bott.	1
Chloroform, botts.	2
Glycerine, bott.	1
Laudanum, bott.	1
Whiskey, botts.	2
Stoppers, rubber, for above, number.	10
Petrolatum, lb.	1
*Pocket case, aseptic, number	1
*Pus-basin, number	1
*Razor, number	1
*Razor-strop, number	1
*Towels, number	2

Contents of Drawers.

Drawer No. 1.	
Bandage, rubber, number.	1
Brush, nail, number.	1
Gauze, sublimated, yds.	2
Goggles, number.	2
*Iodoform sprinkler, number	1
Ligature, catgut, carbolized, spools	3
Ligature silk, cards	5
Needle, thread, etc., in case, case	1
Pencil, indelible, leads for, number.	3
Pins, common, paper.	1
Pins, safety, assorted, doz.	4
Plaster, isinglass, yds.	10
*Speculum for ear and nose, number	1
Tape, piece.	1
*Tape measure, number.	1
*Tourniquet, Esmarch's, number.	1
Drawer No. 2.	
*Case, tooth-extracting,† number.	1
Cotton, absorbent, pkgs.	2
Drainage-tubes, rubber, yds.	3
Plaster, adhesive, 1-in., spools	4
Plaster, adhesive, 2-in., spool.	1
Sponges in bags, bags	2
*Syringe, fountain, number	1
Drawer No. 3.	
Bandages, suspensory, number	2
Beef extract, in 1-lb. can, can,	1
*Brush, shaving, number	1
Cotton, absorbent, pkgs.	2
Medicine measuring glass, number	1
Minim measuring glass, number	1
Needle, sail, number	1
Needle, upholsterer's, number	1
*Pencil, indelible, number	1
*Scissors, number	1
*Surgery, Operative, copy	1
Syringe, p. h. r., number.	2
Tags, diagnosis, 24 in book, book.	1

Food Chest, No. 6.

In this chest, as issued, considerable vacant space is left in order to allow latitude to each medical officer as to the exact character of the supplies he may wish to carry.

The printed plan inside the cover of each gives the general arrangement.

Tins labelled "corn starch," "chocolate," and "arrow-root" are included, although not mentioned in the official list of contents, as it is thought that they may contain articles of more general use.
- Beef extract or an equivalent preparation.
- Candles.
- Condensed milk, in original cans, 8 pounds.
- Soap.
- Vinegar, in 1-quart wicker-covered bottles, 2 bottles.
- Yeast powder, in ½-pound original cans.

Tins for the following articles:
- Beans.
- Butter.
- Coffee.
- Salt and pepper.
- Sugar (2 tins).
- Tea.

Reserve Chest, No. 7.

The contents of this chest will be stated subsequently.

Outfit of Schuehle Ice-Machine as per Latest Contract.

Ice-machine, complete, Jacob Schuehle's patent, capacity 3,000 pounds in 24 hours, consists of:
- 1 double ammonia compressor.
- 1 steam-engine.
- 1 boiler, 20-horse power, complete, with feed-pump.
- 1 ammonia condenser.
- 1 9/16-inch boiler-steel freezing-tank, encased in 1-inch pine flooring, with the requisite number of ice-cans.
- 1 steam condenser, capacity sufficient to furnish in 24 hours distilled water for 3,000 pounds of ice.
- 1 brine-pump.
- 1 patent oil eliminator.
- 1 side-feed lubricator.
- 300 fire-brick.
- Bedplate, necessary pipes, gauges, valves, connections, etc.
- Anhydrous ammonia and lubricating oil sufficient to run the machine for two years.

In most cases additional or improved parts have been purchased for these machines, and this list can be considered as approximate only. The ammonia drum, or cylinder, is a container of the ammonia furnished by contract, and unless purchased from the ice fund does not form a part of the Schuehle machine, being returned when a fresh drum of ammonia is received. The Wood-Bailie machine, of which four are now in use, has an ammonia drum as part of the original machine. See par. 48 and Circular S. G. O., June 13, 1891.

For convenient reference the following lists are appended, although the articles are not issued by the Medical Department:

Issued by the Quartermaster's Department (see par. 51).
- Ambulance.
- Ambulance, harness for.
- Axe.
- Clothing, uniforms, etc.
- Cooking utensils.
- Dippers.
- Flags.*
- Gas-fixtures.
- Hand-cart.
- Hatchet.
- Ladder.
- Lamps, bracket.
- Lamps, hanging.
- Lanterns.
- Lockers.
- Piping for ranges and stoves.
- Range and fixtures.
- Shovel.
- Shelter for meteorological instruments.
- Spade.
- Stoves, heating.
- Tentage, etc.
- Travois.
- Wheelbarrow.
- Wood-saw.

* See A. R. 1848, as amended by G. O. 83, 1880. Except guidons, these flags will rarely be issued.

Issued by the Ordnance Department.
- Blanket bag.
- Blanket bag, shoulder straps, pair.
- Blanket bag, coat straps.
- Canteen.
- Canteen strap.
- Cup, tin.
- Fork.
- Haversack.
- Haversack strap.
- Knife.
- Knife, hospital corps.
- Knife, hospital corps, scabbard.
- Meat can.
- Revolver.*
- Rifle, Springfield, muzzle loading.†
- Shot-gun, Springfield.‡
- Shot-gun, reloading, outfit.§
- Spoon.
- Sword-belt for hospital steward.
- Sword-belt plate for hospital steward.
- Sword frog for belt.
- Waist-belt.
- Waist-belt plate.

* Revolvers will be obtained from the Post Commander for service in an Indian country, when necessary. If it is impracticable to obtain them for temporary service in this way, they may be procured by requisition on the Chief Ordnance Officer of the Department.—Circular S. G. O., April 30, 1891.

† The issue of two Springfield muzzle-loading rifles to each military post for company-bearers' drill is authorized.—Decision Acting Secretary of War, 1888.

‡ "Upon requisition of the Post Surgeon (through the usual military channels), duly approved by the Surgeon-General, the Ordnance Department will issue, for use at posts west of the Mississippi River, a shot-gun with necessary appendages and ammunition for the use of members of the Hospital Corps."—Decision Chief of Ordnance, 1889.

§ The reloading outfit of the shot-gun consists of the following: The articles with * prefixed are expendable, and may be replaced by annual requisitions upon the Chief Ordnance Officer of the Department:
- Brush-wiper, number.. 1
- Canister, tin, for powder, 2-lbs., number..... 1
- Canister, tin, for powder, 5-lbs., number..... 1
- *Cartridge primers, number. 1,000
- *Cartridge shells, 20 gauge, number..... 50
- Charger, adjustable, number... 1
- *Cotton cloth, yard..... 1
- *Cotton waste, lbs..... 1¼
- Drift, number..... 1
- Funnel, number..... 1
- *Gun-wads, No. 18, pink edge, number.... 2,000
- Packing-box, number..... 1
- *Powder, musket, lbs..... 7
- Priming tool (Frankford), number 1
- *Shot, No. 8, lbs 50

Below follows the composition of the tablets, etc., which are referred to in the Supply Table.

Tablets, expendable.

The words tablets and pills are used synonymously throughout the Supply Table:

Alterative.
Mercury protiodide, gr..... 1/5
Opium, gr..... 1/12
Antiseptic:
Mercury bichloride, gr..... 7.7
Ammonium chloride, gr.... 7.3
One tablet to one pint of water makes a 1 to 1,000 solution.
Camphor and Opium:
Camphor, gr..... 2
Opium, gr..... 1
Compound cathartic:
Same as compound cathartic pill.
Compound cathartic, vegetable:
Ext. colocynth, compound, gr..... 1/3
Podophyllin, gr..... 1/4
Pulv. resin scammony, gr... 1/2
Pulv. aloes socotrine, gr.... 1 1/4
Pulv. cardamom, gr..... 1/9
Saponis, gr..... 1/2
Copaiba compound:
Balsam copaiba, gr..... 1 1/2
Resin guaiac, gr..... 3/8
Iron citrate, gr..... 3/8
Oleo-resin cubebs, gr 5/8
Cough:
Extract licorice, gr..... 1/10
Camphor, gr..... 1/25
Acid benzoic, gr..... 1/25
Oil anise, gr..... 1/25
Opium, gr 1/25
Tartar emetic, gr..... 1/60
Each tablet is the practical equivalent of one teaspoonful of brown mixture.
Diarrhœa:
Calomel, gr..... 1/8
Morphine sulphate..... 1/16
Capsicum, gr..... 1/16
Ipecac, gr 1/32
Camphor, gr..... 1/16
Liniment:
Camphor, gr..... 6 1/2
Capsicum, gr..... 6 1/2
Ext. belladonna, alcoholic, gr..... 6 1/2
Dissolve one tablet in one ounce of alcohol.
Peptic:
Pepsin, gr..... 2
Pancreatin, gr..... 2
Bismuth subnitrate, gr..... 2
Tonic:
Iron pyrophosphate, gr..... 1
Quinine sulphate, gr..... 1/2
Strychnine sulphate, gr..... 1/60

Vegetable ration.

DIET.—To the ration of the soldier as described, page 120, third volume of this HANDBOOK, Congress in 1890 added one pound of vegetables, which by decision of the War Department were to be issued as: 1, One hundred per cent. in fresh potatoes; or, 2, eighty per cent. in fresh potatoes, and twenty per cent. in fresh onions; or, 3, seventy per cent. in fresh potatoes, and thirty per cent. in canned tomatoes, or in such fresh vegetables as can be procured in the vicinity of the station, or which it may be practicable to furnish from a distance in wholesome conditions; such as onions, cabbages, beets, turnips, carrots, and squash.

It was further directed that in preparing requisitions for these things, the preferences of the troops will be considered as far as climate, resources of the vicinity, transportation facilities, and season may render practicable.

Under these instructions the food supplied the soldier has been increased by the amount of one pound of vegetables per man, and the Subsistence Department, in issuing, has been guided by the expressed preferences of the troops as to what particular vegetables were supplied, by far the greater proportion being Irish potatoes.

The Irish potato as vegetable ration.

The Irish potato is one of the most abundant of the vegetable foods raised in this country, and it is also one that can be readily transported, and with small danger of injury or loss, as compared with most other vegetables. It is, therefore, to be presumed that it will be largely selected and supplied as food; and concerning it as the vegetable component of the ration, I will principally make comment.

According to the Tables found in Parke's "Hygiene," about three-fourths of the potato consists of water, and one-fifth of carbo-hydrates. One-fiftieth consists of albuminates; one-sixth of one per cent. of fatty material; and one per cent. of salts; so that one pound of potatoes added to the ration adds 0.32 oz. of albuminates; 0.0256 of fatty material; 3.36 oz. of carbo-hydrates, and 0.16 of salts. Adding these amounts to the ration given on page 121–2, Vol. III., of the HANDBOOK, these rations will foot up as follows:

COMPOSITION OF U. S. RATION WHEN INCREASED BY ONE POUND OF POTATOES.

	Albuminates.	Fatty material.	Carbo-hydrates.
	Ounces.	Ounces.	Ounces.
Largest ration of U. S. Army in weight	5.966	1.684	19.296
U. S. Army salt beef ration	4.72117	1.2685	18.7512
Typical ration of U. S. Army	5.197	5.3848	18.872

These amounts may be compared with the amounts in the ration of Moleschott, Pettenkofer and Voit, Ranke, and of the English Army, which amounts were not given, however, in the previous article in terms as below.

	Albuminates.	Fatty material.	Carbo-hydrates.
	Ounces.	Ounces.	Ounces.
Moleschott	4.587	2.964	14.247
Pettenkofer and Voit	4.83	4.12	12.40
Ranke	3.52	3.52	8.46
English Army	3.736	1.44	12.71

Comparison with other rations; United States Army ration increased by addition of one pound potatoes.

If we contrast these figures, it appears that the heaviest ration of the United States Army, increased by the vegetable ration, exceeds in albuminates and carbo-hydrates each of the four rations given in the last table, but is exceeded by each of them in fats, except the ration of the English Army, the fat in whose ration is slightly less. The salt beef ration of the United States Army, also so increased, is in a trifling degree less than that of Pettenkofer and Voit in albuminates, but exceeds all the others in this ingredient; it is less than all the others in fats, but much larger in carbo-hydrates.

The ration given as typical for the United States Army, increased by the vegetable allowance, is much larger than any of the others in albuminates, fats, and carbo-hydrates.

In a paper on the best ration for the soldier, published in the "Transactions of the Ninth International Medical Congress," is found a table giving the mean proportion of the components of seven different rations, which mean is as follows: Albuminates, 4.37 ounces; fatty material, 2.74 ounces; carbo-hydrates, 13.4 ounces. Let us compare with these amounts, the amounts given for what I have termed the typical ration of the United States Army, when increased by one pound of vegetables. The composition of this ration thus increased is as follows:

	Albuminates.	Fatty material.	Carbo-hydrates.
	Ounces.	Ounces.	Ounces.
Meat, half beef	1.245	0.6972	
Meat, half bacon	0.53	4.40	
Bread, half flour	1.314	0.108	6.174
Bread, half hard bread	1.248	0.104	5.822
Beans	0.54	0.05	1.20
Sugar	.....	.....	2.316
Potatoes	0.32	0.0256	3.36
Total	5.197	5.3848	18.872

The increase of albuminates in this ration (5.197 ounces) over the amount contained in the mean of several rations before given (4.37 ounces), equals 0.827 ounce, or nineteen per cent.

The increase in the fatty matter (5.3848 ounces) over that of the mean ration as above (2.74 ounces), equals 2.6448 ounces, or ninety-six per cent., almost double. The increase in the carbo-hydrates (18.872 ounces) over the carbo-hydrates of the mean ration (13.4 ounces) equals 5.472 ounces, or forty per cent. Certainly there can be no doubt of the sufficiency of this last-named ration.

Considering the figures of the ration called the "Largest ration of the United States Army in weight," and the "United States Army Salt Beef Ration," on page 121, Vol. III., REFERENCE HANDBOOK, we find that, when added to the pound of potatoes as above, both of these rations much exceed the "Mean Ration" in the amounts of albuminates and carbo-hydrates, but are less in fats. But the addition or substitution of bacon or salt pork, for fresh or salt meat in almost any proportion that would presumably, or probably, be issued, would bring up the fatty constituents, and still leave the albuminates and carbo-hydrates largely in excess. It is quite certain that in actual service the contingency can never occur when

bacon or salt pork will be wanting as part of the ration, for any length of time.

If, then, the experiments of all students and observers in regard to diet are worth anything whatever, if the experience of feeding armies and large bodies of men teaches aught worthy of reliance, it may be affirmed that the present ration of the United States soldier is larger than is necessary. Manifestly the sin of excess in the ration is less to the disadvantage of the soldier than that of insufficiency; but the same cannot be affirmed as to its advantage to the tax-payer.

Present United States Army ration larger than needed for purposes of nutrition.

The first cost to the United States of a pound of potatoes will not average less than a cent. This alone, to an army of one hundred thousand men, will equal $1,000 per day. To this must be added the cost of transportation to and with the army, and the expenses due to loss. In time of war each of the above items of cost will be largely increased over time of peace, and the cost of transportation is one of the heaviest expenses of the campaign.

Unless it can be shown that the supplying or the eating of unnecessary food possesses certain advantages not due to the final consumption of the food in the processes of nutrition, it may well be doubted whether the legislation which added to each ration one pound of vegetables was wise legislation, even though liberal to the soldier.

Certainly, those who have accompanied an army through a campaign will appreciate the immense additional labor and expense which will be entailed on the Quartermaster and Subsistence Departments if the attempt be made to carry out the law in time of war and supply the vegetables which have been added to the ration. The title of the act giving a vegetable ration is, "An act to prevent desertions from the army and for other purposes."

The foregoing considerations are entirely independent of the question of the desirability and necessity of fresh vegetables as an article of diet. This desirability is undisputed.

On p. 103, Vol. III., REFERENCE HANDBOOK, it is stated that the "surgeon must insist that fresh vegetables be supplied." Although it is said that people have lived, and do live, on animal food alone, or animal food with the addition of food of vegetable origin, but not ordinarily considered as fresh vegetables (flour, etc.), it will not here be denied that green, fresh vegetables are, if not necessary, certainly very desirable as an article of diet.

Vegetables needed as food.

Vegetarians claim that they live on vegetable food, to the exclusion of animal food, with the maintenance of better health than belongs to the consumer of animal food; and green vegetables are beyond doubt often a luxury.

But in the study of the soldier's ration, economy is an important consideration, certainly when its practice cannot be shown to conflict with aught more important.

The nutritive power of vegetables is small in proportion to weight, and the large amount of water they contain (which in the cabbage is nine-tenths or over) will always interfere with their general use as a constituent of the ration of an army in the field.

In time of peace, by company and post gardens, and by the barter or exchange of other portions of the soldier's ration, as has been heretofore shown in this HANDBOOK, the soldier may always have, and does in general have, an abundance of vegetables.

In time of war I believe the *regular daily issue* of a fresh vegetable ration to be almost, if not quite, impracticable; but vegetables may and must be purchased, and issued from time to time, on the recommendation of the medical authorities, as the circumstances may favor their procurement, or as the need may become imperative. This issue should be a special issue to replace other articles of food or in addition thereto.

DRINK.—Not much on the subject of drink need be added to what was said on that subject, p. 123, Vol. III. of this HANDBOOK. It is proper to emphasize the importance of boiling as a purifying process for suspected water. A temperature of 212° F. and upward will destroy the life of the bacillus of cholera and of microbes generally, and this mode of purification is cheap and handy.

Boiling to purify water.

ICE MACHINES.—Since the REFERENCE HANDBOOK was published the Medical Department has supplied ice machines to such Southern posts as were unable to obtain, by purchase, ice for the use of the sick.

The Surgeon-General has announced that these machines "are furnished by the Medical Department to supply ice for the use of the sick in hospital, and not for the comfort or convenience of the garrison at large," and this because such supply for the well belongs to another supply department. Under the regulations issued by the Surgeon-General June 13, 1891, the ice machines are operated under the immediate direction of medical officers.

After the sick were furnished with the needed ice the surplus manufactured was sold to officers, soldiers, and civilians at prices fixed by the officer in charge, with the approval of the Medical Director, these prices being sufficiently high to create a fund from which were met the expenses of the ice manufacture, viz., such expenses as repairs, fuel, oil, ammonia and salt, wages, freight on supplies, etc.

Ice supply.

No action of the Medical Bureau has been more grateful or beneficent to the army than this issue of ice machines and the supply of ice which it has been found practicable to issue to the garrisons at an expense generally of half a cent or less per pound.

A description of the ice machine used will be found under the heading Supply Table in this paper.

CLOTHING.—The soldier's clothing allowance, according to the latest orders of the War Department, is as follows:

ALLOWANCE OF CLOTHING.

Articles.	Year. First. 1st 6 mos.	First. 2d 6 mos.	Second.	Third.	Fourth.	Fifth.	Total for five years.
Helmets and trimmings, complete, number	1	..	..	1	..	..	2
Forage-cap and trimmings, number.	1	1	1	1	1	1	6
Campaign hats, number	1		1	1	1	1	5
Uniform coats, number	1	..	..	1	..	..	2
Trousers, pairs	2	1	2	2	2	1	10
Canvas fatigue coat, number	1	..	1	1	1	1	5
Canvas fatigue trousers, pairs	1	..	1	1	1	1	5
Linen collars, number	4	2	6	6	6	6	30
Dark-blue flannel shirts, number	2	1	2	2	2	2	11
Knit undershirts, number	2	1	3	3	3	3	15
Drawers, pairs	2	1	3	3	3	3	15
Boots, for mounted troops, pairs	1	..	1	..	1	..	3
Shoes, for mounted troops, pairs	1	1	1	2	1	1	7
Shoes, for foot troops, pairs	2	1	2	3	2	2	12
Barrack shoes, pairs	1	..	1	1	1	1	5
Stockings, woollen, pairs	3	1	4	4	4	4	20
Stockings, cotton, pairs	3	3	6	6	6	6	30
Blouses, number	1	..	1	1	1	1	5
Overcoats, number	1		..	..	..	..	1
Chevrons, cloth, pairs	2	.	1	1	1	1	6
Chevrons, gold lace, pairs	1	..	..	1	..	..	2
Stripes for trousers, pairs	2	1	2	2	2	1	10
Stable-frock, for mounted troops, number	1	.	..	1		..	2
Overalls, for engineers and mounted troops, pairs	1	..	1	1	1	1	5
Blankets, woollen, number	1		..	1	..	..	2
Berlin gloves, for mounted troops, pairs	2	2	4	4	4	4	20
Berlin gloves, for foot troops, pairs	4	4	8	8	8	8	40
Leather gauntlets, pairs	1	..	1	..	1	..	3
Suspenders, pairs	1	..	1	1	1	1	5
Band musicians authorized by law are entitled to mounted helmets, and, in addition to the foregoing, to the following articles:							
Trousers, white, pairs	2	1	2	2	2	1	10
Aiguillette and shoulder-knots, number	1	..	..	1	..	..	2
Music pouch	1	..	..		..	..	1

To this allowance must be added canvas mittens and canvas lined caps, and also leggings and cravats.

Cork helmets are supplied to troops, in the first and

third years of their enlistment, in lieu of the campaign hats.

Arctic overshoes and woollen mittens, when issued, will be charged to the enlisted men at cost prices. The necessity for their issue must, however, be certified to by the department commanders. The allowance for these articles is as follows:

Arctic overshoes, one pair in each of the first and third years of enlistment, and woollen mittens, two pairs per annum.

Overcoats made of fur or other suitable material will be issued and accounted for in the manner prescribed by paragraph 1301 of the regulations.

One fur cap and one pair of fur gauntlets will also be issued annually to all enlisted men in the Departments of the Platte, Dakota, and the Columbia, and in other departments, when specially authorized by the department commander, at the prices established for such articles in the annual price-list.

Rubber blankets and ponchos may be issued gratuitously at the rate of one per annum to each enlisted man, until the stock on hand shall have become exhausted.

Enlisted men may draw, whenever in the opinion of the proper officer it may be necessary, during their first year's enlistment, the two woollen blankets to which they are entitled during their service of five years.

The full amount of the allowance as given in the above table the soldier is not obliged to draw, and of what he does not draw, the money value is placed to his credit, and paid to him in money at date of his discharge from the service or at other stated settlement.

The money value of clothing not drawn placed to soldiers' credit.

REPORTS AND RECORDS REQUIRED OF THE MILITARY SURGEON.—Of the reports and records named, page 128, Vol. III., REFERENCE HANDBOOK, the case, diet, and prescription book, No. 10; the register of patient's effects, No. 12; and meteorological reports, No. 13, are no longer required of the surgeon.

The form called "Consolidated Reports of the Medical Department," No. 18, has been done away with and a new form substituted, called a "Report of Sick and Wounded." In certain respects the latter is an improvement upon the former, but retains some of its defects.

To the author it seems that the effort is made to comprise in this report *too much*, and it is to be hoped that some day a simpler form of report of sick and wounded may be adopted for the army. The writer of this paper has had occasion during the past thirty years to pay very much attention to this especial report.

Report of sick and wounded.

Since the remarks were printed concerning said report (page 127, Vol. III., of this HANDBOOK), a paper was read on the subject before the Section of Military and Naval Medicine and Surgery of the Ninth International Medical Congress, and published in its "Transactions." For more detailed arguments on the subject the reader is referred to that paper.

The report of sick and wounded of an army should be as brief as possible, consistently with its useful purpose, because the officer making it must be often, if not always, without the clerical help or the time needful to prepare an elaborate paper.

It is an *army* report, and not a paper specially prepared for the Census Bureau, for the Pension Bureau, or the general statistician, to the aid of all of whom, however, it should come, but solely within its own sphere; not pretending to give information so special in its kind as to be almost certainly inaccurate and unreliable when reported by any other than a skilled observer or student of the specialty.

No one can well do amateur work which interferes with his proper legitimate work if he is interested in that legitimate work and if that work occupies his time. Accordingly it seems wisest to require from the military surgeon, as part of his military duty, such reports only as grow out of and belong to his place as a military surgeon.

The following propositions, which were adopted, and reported by the Section of Military and Naval Medicine and Surgery of the Ninth International Medical Congress to the Congress itself are here again enumerated:

1. The main object of a report of sick and wounded for an army is to give the diseases and injuries, their number, their proportion occurring among the troops and the results thereof, all other objects being incidental and secondary, or better effected in certain cases by special reports.

2. For purposes of convenience this report should be monthly.

3. It is desirable that, for comparison and study, the form of this report should be uniform for all armies and as simple as may be.

4. No nosological arrangement can now be made which commends itself to everyone, and which all will agree on as the only one compatible with scientific knowledge; and, therefore, *that* nomenclature and arrangement of diseases should be adopted which is most convenient for use in the exigencies of military service.

5. In view of the great desirability of an uniform "report of sick and wounded" by all armies, and in the absence of any other form better fitted to fulfil the ends for which this report is made, this Section recommends the adoption of the subjoined "form" in the medical departments of all armies.

The "form" which followed contained the date, place, and mean strength; a list of diseases, by name, occurring, with their result, cure, death, etc.; a report of vaccinations; of discharges on certificate of surgeon, and of deaths, by name; and "directions" how to make out the report.

The nosological table recommended was that of the Prussian army, arranged in fourteen divisions, as follows:

First Division.—General diseases (poisoning).
Second Division.—Diseases of the nervous system.
Third Division.—Diseases of respiratory organs.
Fourth Division.—Diseases of circulatory organs.
Fifth Division.—Diseases of organs of assimilation.
Sixth Division.—Diseases of urinary and sexual organs (excluding venereal).
Seventh Division.—Venereal diseases.
Eighth Division.—Diseases of the eye.
Ninth Division.—Diseases of the ear.
Tenth Division.—Diseases of integument.
Eleventh Division.—Diseases of organs of locomotion.
Twelfth Division.—Mechanical injuries.
Thirteenth Division.—Other diseases, including in the order here named, self-mutilation, attempted suicide, simulation, general debility of body, debility from old age.
Fourteenth Division.—Under observation.

Concerning this form the author remarked that "it is not claimed that this 'form' is perfect, but it is simple, compact, easily understood, easier to make out than any form known to the writer, and contains all the data necessary to determine the proportion of cases of disease or injury occurring in an army, and the results thereof, besides all the data needed to enable proper conclusions to be reached in regard to pensions and similar allowances."

I add that no questions regarding doubtful pathology are involved, and that careful reconsideration leads me to here urge this form upon the favorable consideration of the military surgeon.

In addition to the new Report of Sick and Wounded a few stated reports and records have also been added, to wit: a Monthly Statement of Ice Fund from surgeons in charge of ice machines (to the Surgeon-General); a Semi-annual Return of Record Books (to the Surgeon-General); a Morning Report Book of the Hospital Corps (to the commanding officer); a Monthly Return of Hospital Corps (to the Surgeon-General); a Clothing Account Book of the Hospital Corps; a Descriptive Book of the Hospital Corps.

The last four books and reports have been rendered necessary by the organization of a separate Hospital Corps, under the command of the surgeon. Concerning this corps and its necessity to the field-surgeon further remarks will be made.

HOSPITAL CORPS.—On pages 132 to 139 inclusive, Vol. III., REFERENCE HANDBOOK, under the heading "Care and Removal of the Wounded in Battle," a somewhat extended notice is given of the ambulance corps of various armies, including that of the United States Army.

The ambulance corps of the United States Army as described, *loc. cit.*, had done good service during the great War of the Rebellion, and its operations were a great improvement upon the modes of caring for the wounded and sick in the field in previous wars. Still it had manifest imperfections, the most vital being that it really only existed during war, and that its organization only included, besides its officers, the litter-bearers and drivers.

The most progressive military surgeons of our army, and those whom they could influence to co-operate, did not fail, during the years following the war, to represent to those whom they thought could and would aid them, the necessity of a more comprehensive and permanent organization of a body of men whose sole duty should be the care of the sick and wounded at all times, and particularly their first aid when wounded, and their transportation after injury. Finally, March 1, 1887, an act passed by Congress was approved by the President and became a law.

This law establishing the Hospital Corps is the most important legislation for the Medical Department which has taken place since the Medical Department was reorganized. Upon page 222, Vol. VII., REFERENCE HANDBOOK, appears quite a full article by Pilcher upon the transportation of the disabled on land. This article is mostly devoted to the handling of the wounded in a systematic manner, and the drill of the organized body by whom the wounded must be handled. Incidentally a few words are said concerning the Hospital Corps, independent of its drill, and a few words only, and it seems proper to here treat more fully of that corps, its organization, and its duties other than that of transporting the wounded. The law organizing the Hospital Corps, is textually as follows:

An act to organize the Hospital Corps of the Army of the United States, to define its duty and fix its pay.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the Hospital Corps of the United States Army shall consist of hospital stewards, acting hospital stewards, and privates; and all necessary hospital services in garrison, camp, or field (including ambulance service) shall be performed by the members thereof, who shall be regularly enlisted in the military service; said corps shall be permanently attached to the Medical Department, and shall not be included in the effective strength of the army nor counted as a part of the enlisted force provided by law.

Sec. 2. That the Secretary of War is empowered to appoint as many hospital stewards as, in his judgment, the service may require; but not more than one hospital steward shall be stationed at any post or place without special authority of the Secretary of War.

Sec. 3. That the pay of hospital stewards shall be forty-five dollars per month, with the increase on account of length of service as is now or may hereafter be allowed by law to other enlisted men. They shall have rank with ordnance-sergeants and be entitled to all the allowances appertaining to that grade.

Sec. 4. That no person shall be appointed a hospital steward unless he shall have passed a satisfactory examination before a board of one or more medical officers as to his qualifications for the position, and demonstrated his fitness therefor by service of not less than twelve months as acting hospital steward; and no person shall be designated for such examination except by written authority of the Surgeon-General.

Sec. 5. That the Secretary of War is empowered to enlist, or cause to be enlisted, as many privates of the Hospital Corps as the service may require, and to limit or fix the number, and make such regulations for their government as may be necessary; and any enlisted man in the army shall be eligible for transfer to the Hospital Corps as a private. They shall perform duty as wardmasters, cooks, nurses and attendants in hospitals, and as stretcher-bearers, litter-bearers, and ambulance attendants in the field, and such other duties as may by proper authority be required of them.

Sec. 6. That the pay of privates of the Hospital Corps shall be thirteen dollars per month, with the increase on account of length of service as is now or may hereafter be allowed by law to other enlisted men; they shall be entitled to the same allowances as a corporal of the arm of service with which on duty.

Sec. 7. That privates of the Hospital Corps may be detailed as acting hospital stewards by the Secretary of War, upon the recommendation of the Surgeon-General, whenever the necessities of the service require it; and while so detailed their pay shall be twenty-five dollars per month, with increase as above stated. Acting hospital stewards, when educated in the duties of the position, may be eligible for examination for appointment as hospital stewards as above provided.

Sec. 8. That all acts and parts of acts in so far as they contravene the provisions of this act are hereby repealed.

This law remains unchanged to the present time, with the one exception that the pay of the private, Hospital Corps, has been increased from thirteen dollars to eighteen dollars per month, because it was found difficult to procure for the first named pay men of the acquirements demanded. Immediately after the passage of the law it became necessary to establish the regulations provided for in its fifth paragraph, and the Secretary of War ordered for that purpose a Board consisting of the late Adjutant-General of the army, and three army medical officers, of whom the writer was the senior.

The Board, after a month's consideration, reported a system of regulations which were approved by the Secretary of War, and published to the army. They were incorporated in the new Army Regulations with such changes as from time to time were demanded to facilitate their operation.

Condensed, the points of these regulations important to be here made known are as follows:

Qualifications necessary for privates of the Hospital Corps.

Privates of the Hospital Corps may be enlisted from civilians, or transferred from soldiers of the line of the army. The latter will be the chief source of supply. The transfer will be made on the application of the post-surgeon, which application must show: 1st, That the man must desire to transfer; 2d, that he has served already one year or more; 3d, that he is not married; 4th, his age, and if over forty, his special qualifications as nurse or cook; 5th, his character; 6th, his physical condition; 7th, his habits as to temperance; 8th, whether for existing or prospective vacancy; 9th, the date of expiration of his present enlistment; 10th, his ability to read and write; 11th, his general intelligence and aptitude for the duties of a private of the Hospital Corps.

Neither artificers nor musicians must be recommended for transfer.

In time of peace recruits for the Hospital Corps who have not previously received at least one year's military instruction in the army shall be attached to a company stationed at Fort Monroe, Virginia; Fort Leavenworth, Kansas; or Fort Riley, Kansas, and shall perform all the duties and be subject to all the drill and discipline required of privates in the organizations to which they are attached. After one year's service in the line they may be assigned to duty in the Hospital Corps. The number of privates so enlisted and undergoing instruction shall at no time exceed ten, unless otherwise specially authorized by the Secretary of War.

Qualifications for appointment as acting hospital stewards.

Privates who have served one year or more in the Hospital Corps, and have displayed particular merit, will be recommended to the Surgeon-General for promotion, by the senior medical officer of the command; from those thus recommended acting hospital stewards will be appointed. The candidate for promotion as *acting hospital steward* must pass a satisfactory examination as to his physical condition, moral character, and general aptitude, and in the general prin-

ciples of arithmetic, including decimal fractions and the rules of proportion; in orthography and penmanship; the Articles of War and the regulations affecting enlisted men; pharmacy; care and use of meteorological instruments and hospital and field appliances furnished by the Medical Department; the methods of rendering first aid to the sick and wounded; the ordinary modes of cooking.

To be appointed *hospital steward* the candidate must have served at least one year as acting hospital steward.

Qualifications for the position of hospital steward.

He must then pass an examination, oral and written, on the branches named above, and also in the elementary principles of hygiene, including ventilation, heating, and disinfecting; the principles of materia medica, therapeutics, and minor surgery; the administration of anæsthetics. He must also possess a thorough knowledge of the regulations of the Medical Department.

These examinations must be conducted by commissioned medical officers.

Hospital stewards cannot be reduced to the ranks, but acting hospital stewards may. Their duties are, under the direction of the medical officer, to look after and distribute hospital stores and supplies; to care for hospital property; to compound and administer medicines; to supervise the preparation and serving of food; to maintain discipline in hospitals and watch over their general police; to prepare the hospital reports and returns; to supervise the duties of the members of the Hospital Corps in hospital and in the field; and to perform such other duties connected with their positions as may, by proper authority, be required of them.

Duties of hospital stewards.

From each company in the army four men shall be selected as *litter-bearers*, to be known as *company bearers*.

Litter-bearers, or company bearers.

These men, together with all available men of the Hospital Corps, are to be instructed at least four hours in each month under supervision of the medical officer, in the duties of litter-bearers and the method of rendering first aid to the sick and wounded.

During an engagement, or in an emergency, the company bearers shall, under the orders of their commanding officers, and the supervision of the regimental surgeons, if any are present, give first aid to the wounded or carry them to the rear until relieved by members of the Hospital Corps; when so relieved they shall immediately join their companies. In active service company bearers shall wear as a distinguishing mark a red brassard around the left arm.

Members of the Hospital Corps will be instructed by the senior medical officer of the post at such times (in addition to those previously prescribed) as he may deem necessary. This instruction shall consist of lectures and demonstrations in the methods of rendering first aid to sick and wounded, and of drills in the ambulance service, and as litter-bearers, in accordance with the prescribed manual.

Litter drill and instruction in first aid to wounded.

Members of the Hospital Corps shall not be required to perform any military duties other than those pertaining to their corps. They shall not be required to attend reviews, parades, or other military ceremonies.

Hospital stewards will be assigned in the proportion of one to every post; two, if the post equals six companies; and an additional steward for each additional six companies. An acting hospital steward is allowed also to every post save the smallest. Privates of the Hospital Corps are allowed in the proportion of three to every post; four, if the garrison consists of two companies, and an additional private for each additional two companies.

Members of Hospital Corps, how assigned.

In the field troops shall be accompanied by such number of men of the Hospital Corps as may be determined by the post commander on the recommendation of the post surgeon.

Field Service.

Upon the march or in battle medical officers shall, habitually, be attended by a mounted private of the Hospital Corps, carrying a medical officer's orderly pouch. Hospital stewards, acting hospital stewards, and at least one private of the Hospital Corps in each separate company shall be mounted when serving in the field; and all privates of the Hospital Corps shall be mounted when serving with mounted commands. The Quartermaster's Department will furnish the necessary mounts.

Each private of the Hospital Corps shall carry a canteen of water, a knife of approved pattern, and a simple package of dressings; and, except when serving as an orderly, a Hospital Corps pouch.

In time of war ambulance and field hospital services will be performed by members of the Hospital Corps. The privates of the corps, to perform the duties of litter-bearers, service with the ambulances, and at dressing and ambulance stations, should number at least two per cent. of the aggregate strength of the command. To every ten privates there should be an acting hospital steward, and to every thirty privates a hospital steward.

Hospital and ambulance service in war.

The allowance of ambulances, stretchers, and horse and mule litters are the same as fixed in the law published, p. 137, Vol. III., REFERENCE HANDBOOK, and the medical director of the army and each army corps is also given the control in the terms of that law. The wording of that law is also used in prohibiting the use of ambulances save for the transportation of sick and wounded, and in urgent cases for medical supplies, and all persons save the proper medical officers, the officers, non-commissioned officers, and privates of the ambulance service, or others specially assigned by competent authority, are prohibited from taking or accompanying the sick and wounded to the rear.

Ambulances, stretchers, horse and mule litters.

The medical director or chief medical officer is also again directed, previous to a march or battle, to cause the ambulances to be distributed and managed for the collecting the sick and wounded and conveying them to their destination, and to provide, under the general instructions of the commanding general, for the care of the wounded at dressing and hospital stations, when taken possession of by the enemy, by deciding in advance what medical officers and members of the Hospital Corps shall remain with a dressing or hospital station in case it is abandoned or captured by the enemy.

Medical director manages ambulances and provides for care of wounded after battle.

Privates of the Hospital Corps in the field in time of war will be organized into a company for each brigade, with their hospital stewards and acting hospital stewards, under command of an officer of the ambulance service or a medical officer detailed for that purpose, and will habitually camp near the division hospital, or, if there be none, the brigade or field hospital, to give such assistance as may be needed.

Privates of Hospital Corps organization in field.

They will be assigned, by order of the commanding general or the senior medical officer, to such duties connected with their corps elsewhere as may be required; but on the completion of such duty, or after an action, they will rendezvous at their camp, unless otherwise ordered. In time of action, in the absence of specific orders from the commanding general or proper medical officer, the officer in charge of the company will, under the general instructions which he may have received, himself issue the necessary orders to proceed to the dressing stations, or to the relief and care of the wounded.

For the care and treatment of the sick while in hospital or in transport, members of the Hospital Corps should be allowed as follows:

To general and division hospitals, six privates to every thirty beds, with such number of hospital stewards and acting hospital stewards as the Surgeon-General, with the approval of the Secretary of War, may direct. To a railway hospital train of twenty cars, carrying six hundred sick and wounded, two hospital stewards, six acting hospital stewards, and one hundred privates; and to trains of a greater or less capacity the number should be in the same proportion, to vary, however, at the discre-

Allowance of Hospital Corps in the field or war.

tion of the medical director, according to the distance to be travelled and the character of the cases to be transported. To a hospital boat of three hundred beds, three hospital stewards, six acting hospital stewards, and sixty-five privates; or in like proportion to hospital boats of a greater or less capacity.

DEFINITION OF TERMS.—Treating of the terms used in connection with the Hospital Corps, the Surgeon-General defines them as follows:

Wardmaster.—A private in charge of a ward or wards, wherein are other privates of the Hospital Corps on duty as nurses. This term is usually employed only in general hospitals.

Nurse.—A private who is in charge of patients in a ward. In the ordinary post hospital where but one private is on such duty he may also be in charge of the ward.

Cook.—A private who is in charge of the kitchen and preparation and cooking of the food.

Attendant.—A private who performs other duties than those heretofore enumerated.

Orderly.—A mounted private who habitually attends a medical officer "upon the march or in battle." The employment of an orderly in garrison is not contemplated by existing regulations, and the use of the term must be restricted to service in the field.

A description will here be given of certain articles which are either a part of the outfit of the soldier of the Hospital Corps or ordinarily used by him, and of which the Field Surgeon should have knowledge.

Uniform and Dress.—The uniform is to be almost the same as that of an infantry soldier, with modifications as hereunder.

Trousers for all Enlisted Men of the Hospital Corps.—Of dark-blue kersey, same quality as for non-commissioned officers of the other arms of the service.

Stripes for Trousers for Enlisted Men of the Hospital Corps.—Of emerald green piped with white. Hospital steward's to be one and one-quarter inch wide; acting hospital steward, one inch wide; privates, to be one-half inch wide.

Forage-cap Ornament for Hospital Stewards.—A cross in white metal, inclosed by a wreath in white metal; for acting hospital stewards and privates of the hospital corps, a cross in white metal.

Helmets for Enlisted Men of the Hospital Corps.—Same as for infantry, save that the side buttons shall be of yellow metal with a Geneva cross of white metal. *Device*, a Geneva cross.

Uniform Coats.—Same as for enlisted men of infantry except that the facing shall be of emerald green piped with white; that for acting Hospital Stewards to have a red cross on each side of the collar in front. The uniform dress-coats for all non-commissioned officers shall be made of dark blue cloth of finer quality than for privates.

Chevrons for Uniform Coats.—For a hospital steward, three bars and an arc of gold lace; for an acting hospital steward, same as for a hospital steward, omitting the arc.

Cloth Chevrons for Overcoats and Blouses.—For a hospital steward, three bars and an arc of one bar of emerald green cloth, inclosing a red cross; for an acting hospital steward, the same as for a hospital steward, omitting the arc.

For a Private of the Hospital Corps and for all Persons Neutralized by the Terms of the Geneva Convention.—A brassard of white cloth, sixteen inches long and three inches wide, with a cross of red cloth, two inches long and two inches wide in centre, to be worn on the left arm, above the elbow.

For a Company Litter-bearer.—A brassard of red cloth, to be worn on the left arm above the elbow.

Equipment for a Private of the Hospital Corps.—A blanket-bag, blanket-bag shoulder-straps (pair), blanket-bag coat-straps (pair), canteen, canteen-strap, haversack, haversack-strap, waist-belt, waist-belt plate, meat-can, tin cup, knife, fork, spoon, knife and scabbard (Hospital Corps), package of dressings, and Hospital Corps pouch.

Brassards.—The brassard of the red cross was adopted by the Geneva convention as a badge of neutrality, to be worn by all persons authoritatively serving with the medical department of belligerents. It is therefore of no use in time of peace. It was adopted by the War Department as the distinctive badge for *privates* of the *Hospital* Corps, and being a part of their uniform is to be worn at *all* times.

The duty of the company bearer is defined in Army Regulations, par. 1575, and is limited, except for purposes of drill, to "active service," during which he should wear the badge of his special duty.

As the *company bearer* is merely an official emergency man, he should, when serving in the field, be equipped as is any other soldier of the line, plus a field tourniquet and a package of dressings.

ARMS FOR HOSPITAL CORPS.—The Surgeon-General informs medical officers that when on service in an Indian country they should take steps to arm members of the hospital corps for self-protection against a savage enemy.

The Acting Chief of Ordnance concurs "in the views of the Surgeon-General as to the necessity of arming the members of the Hospital Corps for self-protection when on field service in an Indian country. Post commanders will arm the medical enlisted men when necessary. This will meet the case and relieve the medical officers from making returns for fire-arms when use by their men will only be occasional."

Contents of Knapsack.—One rubber blanket, one woollen blanket, one undershirt, one pair of trousers, two pairs of socks, two pairs of Berlin gloves, one pair of drawers, one blue flannel shirt, one towel, one pair of shoes, toilet articles, tin cup (suspended underneath).

Litter and Sling.—The regulation hand-litter consists of a canvas bed, six feet long and twenty-two inches wide, made fast to two poles seven and a half feet long, and stretched by two jointed braces. The ends of the poles form the handles, nine inches long, by which the litter is carried. The fixed iron legs are loop-shaped, four inches high and one and three-quarter inches wide.

On the left front and right rear handles a half round iron ring is fixed, four and a half inches from the end; between this and the canvas plays the movable ring of the sling.

A cross strap with ring and snap is permanently fastened to the bottom of each pole near the handles, the free (ring) end passing through a staple under the opposite pole. When the litter is open the straps lie transversely under the canvas; when the litter is closed they are passed around it through the free loop of the sling and fastened to the snaps, thus securely closing the litter.

One pair of regulation slings is permanently attached to each litter. They are made of gray woollen webbing, two and one-half inches wide, with a leather-lined loop at one end and a leather strap (with buckle) at the other, the strap passing through a steel swivel, itself attached to the movable ring on the handle.

Hospital and Ambulance Flag.—In November, 1889, it was published to the army in regulations, that:

The hospital and ambulance flags of the army are as follows: For general hospitals, white bunting 9 × 5 feet, with a cross of red bunting 4 feet high and 4 feet wide in the centre; arms of cross to be 16 inches wide.

For field hospitals, white bunting, 6 × 4 feet, with a red cross of bunting, 3 feet high and 3 feet wide in the centre; arms of cross to be 12 inches wide.

For ambulances and guidons to mark the way to field hospitals, white bunting, 16 × 28 inches, with a red cross of bunting 12 inches high and 12 inches wide in the centre; arms of cross to be 4 inches wide.

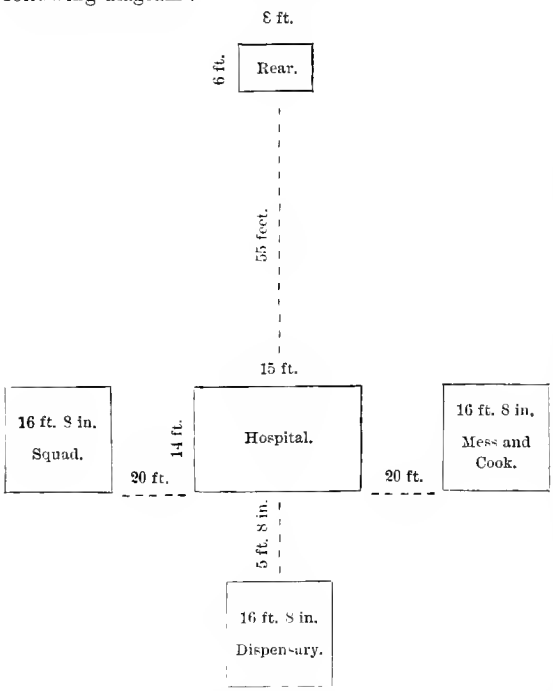
It will be remembered that Article VII. of the Geneva Convention declares that the flag adopted for hospitals, ambulances, and evacuations shall be distinctive and uniform.

Travois.—The travail or travois was briefly treated but not described, page 142, Vol. III., REFERENCE HANDBOOK, and is spoken of by Pilcher in his article on the transportation of the wounded, Vol. VII. As adopted

by the United States Army Medical Department the travois consists of two jointed side-poles seventeen feet long (when extended) connected by two cross-bars, one . . . feet long, placed . . . feet from the front ends, the other . . . feet long, placed six feet behind the first, and of a regulation litter, suspended from the cross-bars by straps provided for the purpose. For transportation, the litter and cross-bars being removed, the poles are closed, the bars laid alongside them and the whole secured by the bar-straps into a package nine feet long which may be carried upon the brackets of the ambulance. A breast-strap and traces accompany the travois. It is drawn by one animal, the rear ends of the poles trailing on the ground.

The service of the travois requires three men, one to lead the animal, the others to watch the litter and be ready to lift its rear poles when passing over obstacles, crossing streams, or going up hill.

Field Hospital.—As adopted by the United States Army Medical Department the canvas of a *regimental field hospital* consists of two hospital tents, and three hospital tent flies, three conical wall tents, one common tent. The hospital tents to be used as a ward; the conical wall tents as dispensary, squad, and mess tents respectively; and the common tent as latrine cover. The tents are most conveniently pitched in cross-shape as per following diagram:



When desired, a fly is pitched over the space between the dispensary and ward, thus affording shelter for those reporting at "Surgeon's Call."

A regimental detachment of the Hospital Corps consists of two non-commissioned officers and eight privates. One army wagon is required to transport a regimental field-hospital complete.

Canvas for a *battalion field hospital* consists of one hospital tent and two hospital tent flies; two conical wall tents; one common tent.

The battalion detachment of the Hospital Corps consists of one non-commissioned officer and four privates. One escort wagon is required to transport a battalion field-hospital complete.

Tentage for medical officers is not included in that for the field hospital. Each medical officer is allowed one wall tent complete.

A hospital tent is fourteen feet long, fifteen feet wide, and eleven feet to ridge, the wall being four and a half feet high; it furnishes comfortable accommodations for six patients, and requires to pitch it a ridge pole and two upright poles, seven long tent pins on each side for the guy ropes, and two on each side for the long guys, eighteen in all. Twenty-four small pins are needed for the front, rear, and walls. The hospital tent should always be pitched first in the field hospital.

Geneva Convention.—Reference to the Geneva Convention has been made in the foregoing, and it particularly behooves the field surgeon to be familiar with its provisions.

During the War of the Rebellion the War Department published to the army "Instructions for the Government of Armies of the United States in the Field," prepared by Francis Lieber, LL.D., and revised by a board of officers.

Therein were contained the following paragraphs particularly interesting to the field surgeon:

35. Classical works of art . . . *as well as hospital*, must be secured against all avoidable injury, even when they are contained in fortified places while besieged or bombarded.

49. A prisoner of war is a public enemy, armed or attached to the hostile army for active aid, who has fallen into the hands of the captor, either fighting or *wounded*, on the field *or in the hospital*, by individual surrender or by capitulation. . . .

All soldiers, of whatever species of arms; . . . *all disabled men* . . . if captured . . . are prisoners of war, and as such exposed to the inconvenienees, as well as entitled to the privileges, of a prisoner of war.

53. The enemy's chaplains, officers of the medical staff, apothecaries, hospital nurses, and servants, if they fall into the hands of the American army, are not prisoners of war, unless the commander has reasons to retain them. In this latter case, or if, at their own desire, they are allowed to remain with their captured companions, they are treated as prisoners of war, and may be exchanged if the commander sees fit.

79. Every captured wounded enemy shall be medically treated according to the ability of the medical staff.

115. It is customary to designate by certain flags (usually yellow), the hospitals in places which are sheltered, so that the besieging enemy may avoid firing on them. The same has been done in battles when hospitals are situated within the field of engagement.

116. Honorable belligerents often request that the hospitals within the territory of the enemy may be designated, so that they may be spared.

An honorable belligerent allows himself to be guided by flags or signals of protection as much as the contingencies and the necessities of the fight will permit.

117. It is justly considered an act of bad faith, of infamy, or fiendishness, to deceive the enemy by flags of protection. Such act of bad faith may be good cause for refusing to respect such flags.

Early in the war, in 1861, and for some time thereafter, captured medical officers were considered prisoners of war the same as the combatants, but later action in regard to captured medical officers was in accordance with the above paragraphs.

The Geneva Convention modifies the above quoted paragraphs slightly in certain directions, which will be patent on reading the original Convention with the articles additional thereto to which it appears the United States have aeceded. The importance of this Convention is such as to demand its appearance in this place.

General Orders, No. 3.

Headquarters of the Army,
Adjutant-General's Office,
Washington, January 14, 1892.

The Convention between the United States, Baden, Switzerland, Belgium, Denmark, Spain, France, Hesse, Italy, Netherlands, Portugal, Prussia, Würtemberg, Sweden, Greece, Great Britain, Mecklenburg-Schwerin, Turkey, Bavaria, Austria, Russia, Persia, Roumania, Salvador, Montenegro, Servia, Bolivia, Chili, Argentine Republic, and Peru; with additional articles: For the

amelioration of the wounded in armies in the field; concluded August 22, 1864; acceded to by the President March 1, 1882; accession concurred in by the Senate March 16, 1882; proclaimed as to the original convention, but with reserve as to the additional articles, July 26, 1882; commonly known as the Geneva Convention, is as follows:

ORIGINAL CONVENTION.

Article 1. Ambulances and military hospitals shall be acknowledged to be neuter, and, as such, shall be protected and respected by belligerents so long as any sick or wounded may be therein.

Such neutrality shall cease if the ambulances or hospitals should be held by a military force.

Art. 2. Persons employed in hospitals and ambulances, comprising the staff for superintendence, medical service, administration, transport of wounded, as well as chaplains, shall participate in the benefit of neutrality, while so employed, and so long as there remain any wounded to bring in or to succor.

Art. 3. The persons designated in the preceding article may, even after occupation by the enemy, continue to fulfil their duties in the hospital or ambulance which they serve, or may withdraw in order to rejoin the corps to which they belong.

Under such circumstances, when these persons shall cease from their functions, they shall be delivered by the occupying army to the outposts of the enemy.

Art. 4. As the equipment of military hospitals remains subject to the laws of war, persons attached to such hospitals cannot, in withdrawing, carry away any articles but such as are their private property.

Under the same circumstances an ambulance shall, on the contrary, retain its equipment.

Art. 5. Inhabitants of the country who may bring help to the wounded shall be respected, and shall remain free. The generals of the belligerent powers shall make it their care to inform the inhabitants of the appeal addressed to their humanity, and of the neutrality which will be the consequence of it.

Any wounded man entertained and taken care of in a house shall be considered as a protection thereto. Any inhabitant who shall have entertained wounded men in his house shall be exempted from the quartering of troops, as well as from a part of the contributions of war which may be imposed.

Art. 6. Wounded or sick soldiers shall be entertained and taken care of, to whatever nation they belong.

Commanders-in-chief shall have the power to deliver immediately to the outposts of the enemy soldiers who have been wounded in an engagement, when circumstances permit this to be done, and with the consent of both parties.

Those who are recognized, after their wounds are healed, as incapable of serving, shall be sent back to their country.

The others may also be sent back, on condition of not again bearing arms during the continuance of the war.

Evacuations, together with the persons under whose directions they take place, shall be protected by an absolute neutrality.

Art. 7. A distinctive and uniform flag shall be adopted for hospitals, ambulances, and evacuations. It must, on every occasion, be accompanied by the national flag. An arm-badge (brassard) shall also be allowed for individuals neutralized, but the delivery thereof shall be left to military authority.

The flag and the arm-badge shall bear a red cross on a white ground.

Art. 8. The details of execution of the present convention shall be regulated by the commanders-in-chief of belligerent armies, according to the instructions of their respective governments, and in conformity with the general principles laid down in this convention.

ADDITIONAL ARTICLES.

Article 1. The persons designated in Article 2 of the Convention shall, after the occupation by the enemy, continue to fulfil their duties, according to their wants, to the sick and wounded in the ambulance or the hospital which they serve. When they request to withdraw, the commander of the occupying troops shall fix the time of departure, which he shall only be allowed to delay for a short time in case of military necessity.

Art. 2. Arrangements will have to be made by the belligerent powers to insure to the neutralized person fallen into the hands of the army of the enemy the entire enjoyment of his salary.

Art. 3. Under the conditions provided for in Articles 1 and 4 of the Convention, the name "ambulance" applies to field hospitals and other temporary establishments, which follow the troops on the field of battle to receive the sick and wounded.

Art. 4. In conformity with the spirit of Article 5 of the Convention, and to the reservations contained in the protocol of 1864, it is explained that for the appointment of the charges relative to the quartering of troops, and of the contributions of war, account only shall be taken in an equitable manner of the charitable zeal displayed by the inhabitants.

Art. 5. In addition to Article 6 of the Convention, it is stipulated that, with the reservation of officers whose detention might be important to the fate of arms and within the limits fixed by the second paragraph of that article, the wounded fallen into the hands of the enemy shall be sent back to their country, after they are cured, or sooner if possible, on condition, nevertheless, of not again bearing arms during the continuance of the war.

[*Articles concerning the Marine.*]

Art. 6. The boats which, at their own risk and peril, during and after an engagement pick up the shipwrecked or wounded, or which, having picked them up, convey them on board a neutral or hospital ship, shall enjoy, until the accomplishment of their mission, the character of neutrality, as far as the circumstances of the engagement and the position of the ships engaged will permit.

The appreciation of these circumstances is entrusted to the humanity of all the combatants. The wrecked and wounded thus picked up and saved must not serve again during the continuance of the war.

Art. 7. The religious, medical, and hospital staff of any captured vessel are declared neutral, and, on leaving the ship, may remove the articles and surgical instruments which are their private property.

Art. 8. The staff designated in the preceding article must continue to fulfil their functions in the captured ship, assisting in the removal of the wounded made by the victorious party; they will then be at liberty to return to their country, in conformity with the second paragraph of the first additional article.

The stipulations of the second additional article are applicable to the pay and allowance of the staff.

Art. 9. The military hospital ships remain under martial law in all that concerns their stores; they become the property of the captor, but the latter must not divert them from their special appropriation during the continuance of the war.

Art. 10. Any merchantman, to whatever nation she may belong, charged exclusively with removal of sick and wounded, is protected by neutrality, but the mere fact, noted on the ship's books, of the vessel having been visited by an enemy's cruiser, renders the sick and wounded incapable of serving during the continuance of the war. The cruiser shall even have the right of putting on board an officer in order to accompany the convoy, and thus verify the good faith of the operation.

If the merchant ship also carries a cargo, her neutrality will still protect it, provided that such cargo is not of a nature to be confiscated by the belligerents.

The belligerents retain the right to interdict neutralized vessels from all communication, and from any course which they may deem prejudicial to the secrecy of their operations. In urgent cases special conventions may be entered into between commanders-in-chief, in order to neutralize temporarily and in a special manner the vessels intended for the removal of the sick and wounded.

Art. 11. Wounded or sick sailors and soldiers, when embarked, to whatever nation they may belong, shall be protected and taken care of by their captors.

Their return to their own country is subject to the provisions of Article 6 of the Convention, and of the additional Article 5.

Art. 12. The distinctive flag to be used with the national flag, in order to indicate any vessel or boat which may claim the benefits of neutrality, in virtue of the principles of this Convention, is a white flag with a red cross. The belligerents may exercise in this respect any mode of verification which they may deem necessary.

Military hospital ships shall be distinguished by being painted white outside, with green strake.

Art. 13. The hospital ships, which are equipped at the expense of the aid societies, recognized by the governments signing this Convention, and which are furnished with a commission emanating from the sovereign who shall have given express authority for their being fitted out, and with a certificate from the proper naval authority that they have been placed under his control during their fitting out and on their final departure, and that they were then appropriated solely to the purpose of their mission, shall be considered neutral, as well as the whole of their staff. They shall be recognized and protected by the belligerents.

They shall make themselves known by hoisting, together with their national flag, the white flag with a red cross. The distinctive mark of their staff while performing their duties shall be an armlet of the same colors. The outer painting of these hospital ships shall be white, with red strake.

These ships shall bear aid and assistance to the wounded and wrecked belligerents without distinction of nationality.

They must take care not to interfere in any way with the movements of the combatants. During and after the battle they must do their duty at their own risk and peril.

The belligerents shall have the right of controlling and visiting them; they will be at liberty to refuse their assistance, to order them to depart, and to detain them if the exigencies of the case require such a step.

The wounded and wrecked picked up by these ships cannot be reclaimed by either of the combatants, and they will be required not to serve during the continuance of the war.

Art. 14. In naval wars any strong presumption that either belligerent takes advantage of the benefits of neutrality, with any other view than the interest of the sick and wounded, gives to the other belligerent, until proof to the contrary, the right of suspending the Convention, as regards such belligerent.

Should this presumption become a certainty, notice may be given to such belligerent that the Convention is suspended with regard to him during the whole continuance of the war.

Art. 15. The present act shall be drawn up in a single original copy, which shall be deposited in the archives of the Swiss Confederation.

The additional articles have been acceded to by the United States, and signed on behalf of Great Britain, Austria, Baden, Bavaria, Belgium, Denmark, France, Netherlands, North Germany, Sweden and Norway, Switzerland, Turkey, and Würtemberg, but will not acquire full force and effect as an international treaty until the exchange of the ratifications thereof between the several contracting states shall have been effected.

II. The foregoing Convention and additional articles are published by the order of the President, who commands that the original Convention and the first five of the additional articles shall form part of the "Instructions for the Government of Armies of the United States in the Field," as published in General Orders, No. 100, 1863, from this office.

III. By direction of the Secretary of War the provisions of the Geneva Convention incorporated into the "Instructions for the Government of Armies of the United States in the Field" in the preceding paragraph will form part of the examination of captains of the line, Quartermaster's and Subsistence Departments, as prescribed under the head of "Military Law" in the Memorandum from this office dated October 5, 1891.

By command of Major-General Schofield:

Official. J. C. KELTON, *Adjutant-General.*

DRILL OF THE HOSPITAL CORPS.—In the past six years much attention has been given to the drill of the hospital corps. Several systems and manuals of drill have been prepared by different military surgeons, and more than one has been adopted by the medical department of the army, to be in its turn discarded, so that the whole subject may be considered as yet undecided and in a state of transition. The composite of all these efforts of individuals, as well as those of a Board convened by the War Department for the purpose of preparing a manual of drill for adoption in the United States Army, is about to appear in a new manual to be prescribed to the army as its official hospital corps drill. The writer has examined carefully every one of these systems of drill, and has found each to possess merit.

I propose to present some remarks pertinent to one phase of the subject, and that is the effect of drill on separate individual action. In so far as regards those duties of the hospital corps relating to the handling and first aid to wounded, the drill has acted unfavorably.

Since the presentation to the Hospital Corps of our army of its first manual of drill, the writer of this paper, in the discharge of his official duties as Medical Director, has made many formal inspections of the Hospital Corps and its drill, at between thirty and forty different military posts, extending from Pembina to San Diego, Cal. At these inspections a suppositious case has been presented at the drill to a set of "fours," in which a great emergency had occurred, a wounded man bleeding rapidly, or some other case demanding prompt and rapid action, and this view of the case was emphatically presented to the "fours" in words. In nearly every case the action of the "four" has been slow and deliberate, precisely as they had been drilled, while in the meantime the wounded man might have perished from lack of aid. In all these cases the officers under whom the men had been drilled informed me that they had not failed to impress, previously, on the men drilled the necessity of promptness of action in such emergencies, and further expressed surprise at the inappropriate action of their men of which I speak.

Now, it is quite apparent that nothing will account for the display of the want of judgment, and for the improper action in these cases but the *drill*. The men had been "drilled into" a certain routine, and so "drilled" that they were unable to depart therefrom when circumstances required that they should.

This view of the case acquires additional force when we consider what a drill is, and what for.

Drill seems to be the systematic instruction in certain acts which can be effected in different ways, but which should be always done in the same way, and in the one particular manner taught at the drill; or else acts that are performed by a number of persons together, and in harmony, and therefore best performed in a methodical, systematic manner.

Drill in general; what it is for.

Drill does not include the very large number of acts which are seldom best performed in one single way, or by a single person, but whose best manner of performance, in different cases, will vary widely, according to circumstances, and this best manner be selected by the exercise of individual judgment. This distinction clearly appears in early definitions of drill, though not made so prominent in some later definitions.

Wilhelm speaks of drill as in general the "exercises through which soldiers and sailors are passed to qualify them for their duties."

Webster's Dictionary gives the military meaning as "the act or exercise of training soldiers in the military art, as in the manual of arms, in the execution of evolutions and the like." Worcester's definition is, "the instruction of officers and soldiers in the exercise of

the firelock, and in the first principles of field movements."

Where men perform military exercises in masses, such as companies, platoons, or sets of fours, these exercises are best taught by drill and performed in an undeviating manner. Where the exercise, however, is to be performed individually, and demands individual judgment, as in sharp-shooting, or giving the first aid to a wounded soldier, it is best done independently of drill.

There is something very attractive about the drilling of men in a military manner—the giving them orders and watching them move in obedience thereto,—and any drill manual for the Hospital Corps must, of course, treat of the marching movements of the men and their handling of the litter, as well as of the first aid to the wounded, unless, as would be proper, the two subjects are embraced in different handbooks. Hence the danger, and the tendency which really has manifested itself, of making the military movements of the members of the Hospital Corps too important and conspicuous a part of their education, to the neglect of the most important part of their duty when in the field, viz.: the first care of the wounded, the carriage of whom, on a litter, does not constitute the greatest part of such first care, though one necessary portion.

Military movements made too conspicuous by the drill.

A certain amount of drill is necessary to a soldier of the Hospital Corps; but one of the qualifications for a private of the corps has already been stated to be service in the line of the army long enough for the acquirement of knowledge of the drill. Any subsequent drill can only serve to familiarize the man with concerted management of the litter, the ambulance, and the dummy, while in these directions it accustoms and prepares the squad of litter-bearers to act intelligently together.

But the first aid of the wounded is a very important part of the duty of the private of the Hospital Corps, and the drill is only one and not the most effective mode of teaching him any part of this. The regulations have attempted to guard against the promotion to undue importance of drill over teaching by their very terms. They say that the company-bearers, and men of the Hospital Corps, shall be "instructed" in "the duties of litter-bearers and the methods of rendering first aid to the sick and wounded." And "the instruction," in further terms, is directed to consist of "lectures and demonstrations in the methods of rendering first aid to the sick and wounded, and of drills in the ambulance service, and as litter-bearers, in accordance with the prescribed manual."

Importance of "first aid to sick and wounded," in the system in which Hospital Corps men should be instructed.

As, however, it became manifest that undue prominence was given to drill as compared with other instruction, the Surgeon-General last year issued the following judicious directions:

"As the object of this drill is the instruction of members of the Hospital Corps and company-bearers in the methods of moving, carrying, and otherwise handling the disabled, it should be conducted personally by a medical officer, who will combine with it instruction for rendering first aid in emergencies. While the military element in litter drill is desirable—and indeed essential—a knowledge of methods in rendering first aid is indispensable to practical efficiency in the corps. For this reason the hour devoted to drill should be largely given to object-lessons and demonstrations, especially in the methods to be used for the arrest of hemorrhage, the application of temporary dressings to fractures and wounds, methods of artificial respiration, etc., a dummy being used for this purpose whenever practicable.

"The object of instruction to company-bearers is 'to insure the constant presence, in each company, of a number of men who can, in emergencies, render temporary aid to the sick or wounded of their organizations;' and 'their duty during an engagement' . . . is to 'carry them to the rear until relieved by the members of the Hospital Corps.' They should, therefore, be instructed primarily and by object-lessons, as far as practicable, in first aid, litter-drill being subordinate to this important knowledge."

I have thus endeavored to impress upon the reader the view that, while instruction of the litter-bearer and private of the Hospital Corps, in all the subjects named in the regulations is of the utmost importance, yet the drill in military movements is of less importance than, and should be subordinated to, instruction in succor and first aid to the sick and wounded. *Joseph R. Smith.*

FLUORESCEÏN (Resorcin-phthalein Anhydride). This is one of the numerous coal-tar products. It results from the union of resorcin and phthalein when heated to the melting-point in equal parts by weight. The chemical formula is $(C_6H_3)(OH)_2(CO)_2$. It is a yellowish-red crystalline powder, sparingly soluble in water, more soluble in an alkaline solution, showing a beautiful green fluorescence.

It possesses the property of adhering to the tissue beneath the epithelium of mucous membranes and imparting to it a deep green color, while the epithelial covering is in no way affected. Advantage was taken of this by Dr. Straub, a Netherlands army surgeon, to detect lesions of the eye, who found that the most minute destruction of tissue could be clearly defined. The value of this discovery was made known to the profession by Dr. Thomalla, of Friedland, *Centralblatt f. prak. Augenheilk.*, November, 1889. Dr. R. L. Randolph (*Johns Hopkins Bulletin*, April, 1890) reports his experience with it, for this purpose, with favorable results. A solution of ten grains of fluoresceïn, with fifteen grains of bicarbonate of sodium to the ounce of distilled water is prepared, and a few drops placed in the eye on the cornea. Where the membrane is intact no trace of the coloring matter is left, but where the slightest abrasion exists, the parts are impregnated with the stain and the injury distinctly mapped out. After washing the eye with water, whenever a discoloration exists, some lesion is present, and if any foreign body is present its size and extent is quite evident by a green ring formed around the substance. In ulcers of the cornea the same positive results were always obtained by Dr. Randolph. In simple superficial keratitis the color was made less distinct; in parenchymatous keratitis the results were negative. Dr. Thomalla had found that in acute glaucoma the disturbances of the cornea that attend this affection could be detected and the diagnosis confirmed. Dr. Randolph did not succeed in detecting any changes in two cases in which he used the solution.

The depth of the coloration depends upon the extent of the wound. When superficial, only the exposed tissue is affected, but when the destruction of tissue is deeper the coloring fluid is absorbed by the open vessels, and the staining radiates from the wound. In ulcers and minute abscesses the coloring matter is restricted by the walls of the diseased spots. Cicatricial tissue is not affected, and the opaque spots of old lesions may be distinguished from those of recent origin. Some experience is required to detect the slighter abrasions and estimate the various degrees of discoloration. Other observers have obtained the same satisfactory action without any unfavorable results. The application is perfectly unirritating, and may be used when the most acute inflammation exists. A potash solution may be prepared, and is preferred by some to that of soda. *Beaumont Small.*

FOOD AND DRUG INSPECTION. MODERN LEGISLATION RELATIVE TO FOOD AND DRUG INSPECTION.—In the third volume of the REFERENCE HANDBOOK articles were published on the subject of "Adulteration of Food and Drink," and upon "Legislation respecting Food and Drug Adulteration," which fully set forth the inspection upon those topics up to the date of their publication. The present article will, therefore, be chiefly devoted to the subject of the efficiency of such legislation to provide protection against this species of crime, and to the amount of work accomplished under such laws.

Popular knowledge upon the subject of food adulteration is undoubtedly derived to a great extent from the occasional publications of the daily press, which are

too often of a very sensational character, exaggerating not only the extent of adulteration, but also the comparative ratio of harmful adulteration to that which is merely fraudulent in its character. Fortunately these publications are not so common as they were a few years ago. It is but ten years since a public document, in commenting upon this subject, stated that "fraudulent adulteration is but little more common than injurious adulteration." An examination of the food supply of almost any community at the present day would undoubtedly show the incorrectness of this statement.

England.—The following statement from the Twenty-first Annual Report of the Local Government Board for 1891–92 shows the advantages of food and drug inspection in England and Wales since the beginning of operations under the Food and Drug Acts in 1876:

The total number of analyses of food and drug samples made in 1891 was 29,028, or about 1,600 more than in the previous year. The increase has been quite constant during the past twelve years. In the five years 1877–81 the average number of samples examined was 16,688, or one to every 1,520 of the population; in 1882–86 it rose to 21,772, or one in 1,237; in 1887–91 it was 26,846, or one in 1,060; while in 1891 it was 29,028, or one in 999. In London one sample was examined for every 580 persons, and in the provinces one for every 1,140. But in some quite populous districts the provisions of the Acts were not carried out, and in commenting upon the neglect of the authorities in these districts the Board says: "It is surprising that the local authorities in these and many other cases are content to leave the inhabitants without that protection against fraud by the sale of adulterated food, which the exercise of the statutory powers conferred on the authority would be likely to insure."

The following table shows that a decided improvement has taken place in England since the Food and Drug Acts went into operation:

RESULTS OF EXAMINATIONS MADE IN ENGLAND AND WALES BY THE PUBLIC ANALYSTS, UNDER THE FOOD AND DRUG ACTS, 1877–91.

Character of samples.	Number of samples examined in 1891.		Percentages of adulteration.				
					Five-year periods.		
	Total.	Adulterated.	1891.	1890.	1877–81.	1882–86.	1887–91.
Milk	12,151	1,633	13.4	12.8	21.1	16.7	13.2
Bread	799	8	1.0	0.7	6.6	3.4	1.4
Flour	427	1	0.2	0.6	2.5	0.5	3.0
Butter	3,558	551	15.5	11.5	13.9	17.9	13.4
Coffee	1,684	287	17.0	15.3	18.6	17.8	14.8
Sugar	171	8	4.7	13.8	1.2	.....	4.6
Mustard	689	60	8.7	7.1	17.4	14.5	9.2
Confectionery, etc	403	11	2.7	....	2.8	2.7	3.2
Pepper	1,452	41	2.8	5.6	.....	.....	7.5
Tea	412	....	....	....	.....	.....	0.1
Lard	1,107	26	2.3	4.0	.....	.....	7.9
Wine	51	2	3.9	7.7	14.2	4.4	4.7
Beer	268	11	4.1	2.0	5.4	3.0	2.6
Spirits	3,139	600	19.1	18.1	34.9	22.3	18.5
Drugs	740	121	16.4	14.5	22.0	13.6	13.1
Other articles	1,967	180	9.2	5.6	....	....	7.5
Total	29,028	3,540	12.2	11.2	16.2	13.9	11.7

The foregoing table shows a slight retrogression since 1890. But the three five-year periods show a decided improvement, comparing the earlier with the latter.

The comments of the Local Government Board show that the practice of milk adulteration in the cities of England differs but little from that which prevails in large cities of the United States.

The whole number of samples of milk examined in England in 1891 was 12,151, or about two-fifths of all samples of food examined. Of these 1,633, or 13.4 per cent., proved to be adulterated. As might be expected, the samples from cities were much more adulterated than those from the country districts.

In London the percentage of adulterated samples was 21.5, ranging from 0 in St. James, Westminster, and other districts, up to 47.2 per cent. in Lambeth. In other large cities the results of analysis were more favorable, Manchester having but 4.7 per cent., Leeds 4.2, and Salford 1.3; while Liverpool and Birmingham had, respectively, 17.6 and 17.9 per cent.

Part of this difference undoubtedly may be accounted for by diversities in the practice of the inspectors, for while one takes samples only from those retailers whom he suspects of adulteration, another may buy from all dealers in his district. Some, again, are not sufficiently careful to conceal their official character, and it is evident that an inspector who makes purchases himself, in a place where he is known, is much less likely to be supplied with adulterated milk than one who employs a deputy for the purpose.

Out of the 1,633 samples of milk reported as adulterated, 989 were the subjects of legal proceedings. In 866, fines were imposed amounting to £1,443 (about $7,025).

The percentage of samples of adulterated butter increased from 11.5 per cent. in 1890 to 15.5 in 1891, notwithstanding the existence of stringent laws similar to those in force in the United States.

The number of samples found to be adulterated was 551, and 394 penalties were inflicted, amounting to £630.

Of the 1,684 samples of coffee examined, 287, or 17 per cent., were adulterated, and of these the Board says: "The proportion of genuine coffee was in some instances as little as 30.15, or even 5 per cent. It is possible that, as is often asserted in defence of the practice of selling these mixtures, some persons consider that the flavor of chicory improves the coffee. But as no special skill is required to mix the two articles, it would certainly be more economical for the consumer to buy his chicory separately, at its market value of about twopence a pound, rather than to pay about six times that price for it under the name of coffee. The penalties were generally very low, occasionally as little as five shillings."

The use of poisonous pigments in England, as elsewhere, appears to have nearly or quite disappeared under the protective action of the Food and Drug Laws. The principal adulterant found in lard was cotton-seed oil.

About one-fifth of the samples of spirits examined were found diluted, but in very few instances had anything but water been added.

The amount of drug adulteration found was 16.4 per cent. (121 samples out of of 740), of which the Board says: "Considering that the difference between pure and adulterated medicine may conceivably be a matter of life or death to the patient, it is desirable that still more should be done in this direction."

The articles not specified were oatmeal, vinegar, arrow-root, cheese, cocoa, olive-oil, yeast, canned peas, ginger, etc.

Of 412 samples of tea examined, not one was found adulterated.

The report of the Public Analyst of Kent for 1891 is worthy of notice. He says: "The steadygoing practice of diluting milk and spirits by the addition of water probably will always continue more or less, as the law is put in force; but there are other often most ingenious forms of adulterations, introduced as special branches of industry, which arise anew, for a time flourish, and then gradually die out. This was the case with the addition of cotton-seed oil to lard, and the substitution of margarine for butter, of powdered olive-stones for pepper, the fact being that the practice of adulteration has become a fine art, scientific knowledge and technical skill being applied to the subject as perseveringly, and, indeed, as successfully, as the same things are being employed in other more legitimate connections. 'Works chemists' of the highest skill in each special department of the food trade are continually engaged in the endeavor to produce articles that can be sold at a greater profit than the things they resemble, at perhaps a less price. This gives rise to a perpetual conflict between the falsifier on the one hand, and the public analyst on the other, in which the latter, in some respects is placed at a great disadvantage, for whereas every move

and method on his part that is devised to advance the art of detection of adulteration is done openly in the face of the scientific world, the arts of the adulterator are practised and perfected in secret. In point of fact, the most refined and successful processes that have been introduced for the falsification of food have been devised in view of, and with the express design to elude, those means of detection which from time to time are discussed and published in the "Transactions" of our scientific societies. This will explain how it comes about that, from time to time, new methods of adulteration are sprung upon us, and for a while a new fashion in adulteration sets in, until in turn, by the invention of new processes or by the perfecting of old ones, detection of the new-fashioned mode of adulteration is made possible, and a check thereby put upon the evil practice, which in course of time dying out is followed by other perhaps more cunning devices, and so it goes on, year by year, an everlasting see-saw of attack and defence, from all of which it naturally follows that the pursuit of the public analyst, day by day, becomes more onerous and more exacting."

Paris.—The work of examining the food supply of Paris has been conducted at the Municipal Laboratory, on the north bank of the Seine, during the past twelve years. When the writer visited this establishment in 1891 it presented the appearance of a busy workshop in which is employed a large force of skilled chemists. Professor C. Girard is the chief chemist in charge. Two printed reports of this laboratory have been published, dated 1882 and 1885.

By decision of the Municipal Council gratuitous qualitative analyses are made at this laboratory of such articles of food and drink as are deposited at the laboratory for this purpose. The greater part of the articles examined is collected by inspectors authorized to visit shops and markets where food is sold, for the purpose of making collection of such samples. These inspectors also have authority to destroy unsound food. Their collections are generally made from such kinds of food preparations as are suspected of adulteration or are especially liable to this species of fraud. Hence the monthly bulletins issued from the laboratory do not represent the actual condition of the markets, since many articles of food are not liable to adulteration. The number of articles examined in each year amounts at present to more than 20,000 annually. The scope of the analyses embraces several articles in common use besides food, such as children's toys, wall-paper, cooking utensils, preparations used in embalming, coloring matter, cosmetics, and illuminating oils.

The following condensed statement, compiled from the monthly bulletins for the eleven months ending May 31, 1892, will give a fair illustration of the work accomplished in Paris during that period: Number of visits made to markets and shops, 45,394; amount of meat and fish destroyed, 327,025 kilogrammes, or about 360 tons; amount of vegetables and fruits destroyed, about 1,000 tons; amount of mushrooms, tomatoes, etc., destroyed, about 295 tons; amount of butter and cheese destroyed, about 1½ ton; complaints before justice, 200; number of articles submitted to examination, 19,928; of these 7,015 were samples of wine, more than half of which were found to be adulterated by the addition of water, alcohol, sugar, coloring matters, plaster, salicylic acid, or other articles.

The other articles were chiefly the following: 97 samples of vinegar, of which 36 were adulterated; 688 samples of beer, of which only 1 was adulterated; 109 samples of cider, of which 45 were adulterated, either by dilution, coloring matter, or other means; 410 of distilled liquors, of which 240, or 585 per cent., were adulterated in various modes; 639 samples of drinking-water, of which 173 were unfit for use, either in consequence of pollution by organic or mineral ingredients; 4,315 samples of milk, of which only 279, or but little more than six per cent., were found adulterated by skimming or watering; of 156 samples of syrup, 74, or nearly half, were adulterated with glucose or coloring matters; of 985 samples of butter, 241, or 24 per cent., were adulterated by the addition or substitution of other fats; of 260 samples of salad oil, 111, or 42 per cent., were adulterated; of 372 samples of flour, only 11, or 3 per cent., were adulterated; of 134 samples of bread and cake, 44 were condemned on account of being mouldy or badly baked; of 253 samples of sugar and confectionery, 26 were adulterated; of 24 samples of honey and preserves, 10 were adulterated with coloring matters; of 262 samples of chocolate and cocoa, 99 were adulterated with foreign fats and other substances; of 268 samples of coffee, chicory, and tea, 42 were adulterated; of 1,344 samples of spices, 83, or 6 per cent., only were adulterated; of 185 samples of preserved meats, 63 were adulterated; three children's toys, out of 13 examined, were condemned on account of dangerous coloring matter; of 346 cooking utensils, 110, or nearly one-third, contained lead; of 737 samples of illuminating oil, 88 were below the standard. Only 2 samples of drugs were examined and both were found good.

The chief difference in the experience of the Paris inspection and that of Massachusetts consists in the low ratio of adulteration in milk and in spices in Paris. The former is probably partially due to the existence of a lower standard of milk solids in Paris.

Hamburg.—The International Review of Food Adulterations (published at Amsterdam) reports that at Hamburg, in 1890, of 758 samples of butter examined, 282 were adulterated; 25 samples of milk out of 44, and 17 samples of coffee out of 27 were adulterated. Of the cases of butter adulteration 185 were convicted, 9 were acquitted, and the remainder were under consideration. The chemist characterizes the extent of butter falsification as "deplorable."

Liège.—M. de Molinari, Director of the Laboratory of Liège, Belgium, reports 2 samples of coffee adulterated from thirty to fifty per cent.; 7 samples of milk, 8 of butter, 2 of pepper, 4 of mustard, 2 of fruit syrup, 4 of liquors, and 4 of beer were adulterated. Fines were imposed from 5 to 100 francs each.

Constantinople.—M. P. Apéry, Government Chemist at Constantinople, reports, as the result of examinations from March to December, 1891: 4 samples of meat, damaged; 4 of fat, rancid and old; 8 of butter, mixed with foreign fats; 25 of coffee, mixed with roasted cereals; 1 of olive-oil, old and rancid; 13 of milk, watered; 2 of cheese, 1 of drinking-water, polluted and unfit to drink; 1 of vinegar, containing wood spirit; 2 of flour, mixed with bean flour; 1 each of cream of tartar, saffron, and glycerine, adulterated.

Strasburg.—Dr. Amthor, of Strasburg, reports for the year ending April 1, 1891: Of 27 samples of *suspected* milk, 16 were adulterated; of 32 samples of butter, 8 were spurious; of 26 samples of confectionery and chocolate, 8 were adulterated; of 37 samples of canned food, 19 were adulterated, chiefly with copper. In two of these fines amounting to thirty marks were imposed ($7.50). Of 12 samples of vinegar, all were good. No trichinæ were found in the hams. Of 59 fruit syrups, 18 were adulterated, the adulterants being chiefly coloring matter and glucose; some were entirely artificial. Four fines of 145 marks were imposed ($35). Of 92 samples of spices, 11 were adulterated; all samples of honey and of cheese were good; of 9 samples of olive-oil, one was adulterated, and a fine of 10 marks imposed. Of 58 samples of lard, 18 were adulterated with cotton-seed oil and stearine. Seven fines were imposed, amounting to 263 marks. Of 356 samples of wine, 32 were bad and 14 suspicious; the adulterants were mainly water and alcohol. Two fines were imposed, amounting to 2,600 marks! also six months in jail! Of 98 samples of sausages, 18 were adulterated with flour, for which 6 fines were imposed of 160 marks in all. For having the fittings of beer-pumps in bad condition, 13 fines were imposed of 50 marks. All samples of petroleum were found to be of good standard quality. Cooking utensils, examined under a law of 1887, were found to contain lead and zinc. Other articles examined were coloring matters injurious to health, cosmetics containing lead, tubes for conduct-

ing beer and wine, nipples of nursing-bottles, etc. The total number of samples examined was 1,322.

Austria.—The Director of the Laboratory at Vienna, Dr. M. Mansfeld, reports, for the year ending August 24, 1891, out of 447 specimens that 160, or 35 per cent., were adulterated. The samples examined were bread, milk, butter, liquors, tallow, cocoa-butter, vinegar, preserves, coloring matters, fruit-juice, spices, compressed yeast, honey, coffee, flour, and olive-oil.

Dr. M. T. Lecco, Official Government Chemist of Belgrade, reports upon the following analyses of food and other articles for the year ending October, 1892:

	Number of samples examined.	Adulterated or of bad quality.
Bread	21	1
Milk	571	39
Cream	42	20
Butter	8	1
Lard	23	1
Water	23	2
Salad oil	68	28
Sausages	15	4
Cake	4	1
Wine	138	10
Brandy	77	9
Vinegar	28	16
Ground coffee	5	5
Whole coffee	7	3
Pepper (ground)	85	29
Pepper (whole)	1	..
Cinnamon	47	28
Sugar	28	1
Crockery ware	8	6
Metallic faucets	4	2
Cosmetics	18	9
Miscellaneous	135	16

The chemist states that the greater part of these articles were falsified by the addition of substances which cheapened their value.

The articles which were harmful to health were adulterated wines, cake colored with chrome yellow, brandy containing an excess of amylic alcohol, cosmetics containing corrosive sublimate and compounds of lead; metal faucets containing twenty-five to thirty-three per cent. of lead.

Amsterdam.—Drs. Coster and Mazure, Government Inspectors at Amsterdam, reported, in 1890, that out of 31 specimens of dried apples examined, 24 contained zinc in variable proportions; dried pears also were found to contain the same; the supposed cause being the drying of these fruits in galvanized (zinc-coated) vessels. In mineral waters they found minute traces of metals, chiefly copper. Out of 804 samples, 577 had no metallic poison.

They examined 1,781 specimens of pork, and none of them contained trichinæ. Of this number 1,090 were from America.

Switzerland.—In Switzerland the work of examining articles of food and drink is well organized by the appointment of a competent chemist in each Canton, whose duties embrace the analysis of all articles in domestic use wherein a chemical analysis may be required.

In the summer of 1891, the writer visited the laboratories of the Cantons of Berne and Lucerne, and found them well equipped and intelligently conducted. The Swiss method of work would form a good model for conducting a laboratory for food analysis in any American city.

Dr. Ambühl, Canton Chemist of St. Gall, examined, in 1890, 1,269 samples of all sorts. Out of 96 samples of milk, 9 were diluted with water from 10 to 35 per cent. In his examinations of samples taken direct from the cow, he found one which contained only 0.45 per cent. of fat instead of 3 or 3.5, and 8.9 of total solids in place of 12.5, or 13 per cent., and says of this sample: "If I had not known that this milk was drawn directly from the cow, as such, I should have decided that it had been both skimmed and watered. Such milk should not be considered as an article of sale, but as a *pathological secretion.*"

In commenting upon the use of poisonous salts of copper as a coloring matter for preserved peas and other vegetables, he says, "Food should not be made to assume a good appearance to the injury of health."

The Canton Chemist of Geneva, in his quarterly report for the last three months of 1891, reports upon the analyses of 274 samples, 215 of which were of wine—165 red and 50 white; 49 were plastered and 147 not plastered. They were further classified as 87 good, 108 medium, and 20 inferior; 20 were reported as injurious to health. Of 10 samples of butter, 7 were good and 3 adulterated; of 14 samples of water, 7 were potable and 7 unfit for use; of 4 samples of milk, 2 were pure and 2 adulterated; of 13 samples of sausage-meat, 10 were good and 3 bad; of 6 samples of spices, all were pure.

Dr. Schaffer, Canton Chemist of Berne, Switzerland, reported upon the following articles in 1890 and 1891, from which it appears that the scope of the Canton chemist's authority extends to nearly all articles in domestic use as well as to food and drugs.

Articles examined.	Number examined.		Number found adulterated.	
	1890.	1891.	1890.	1891.
Ammoniac	....	2	....	....
Apples, dried	2	....	1	....

Water, including mineral waters	123	110	24	28
Wine	353	388	78	74
Wool	3	....	3	....

In addition to the foregoing the chemist reports upon several proprietary articles, such as Putzwasser for cleaning brass; hair-dye, containing nitrate of silver; salve for burns; mixture for erasing writing; powder for removing acid taste from wine (carbonate of lime), and antidotes for erysipelas.

Massachusetts.—The following summary presents in a condensed form some of the results of the work of food and drug inspection in Massachusetts by the State Board of Health during the past nine years of its work in this direction :

Summary.	Years.									Total.
	1883.	1884.	1885.	1886.	1887.	1888.	1889.	1890.	1891.	
Number of samples of food examined	695	1,962	3,771	3,438	4,870	4,904	4,854	5,585	4,870	34,949
Number of samples found to be pure	363	779	2,180	2,186	3,163	3,385	3,213	3,771	3,206	22,246
Number of samples found to be adulterated, or not conforming to the statutes	332	1,183	1,591	1,252	1,707	1,519	1,641	1,814	1,664	12,703
Percentage of adulteration	47.8	60.3	40.3	36.4	35.1	30.9	33.8	32.5	34.2	36.3
Number of samples of milk examined (included above)	218	1,123	2,219	2,085	3,081	2,825	3,219	3,256	2,726	20,732
Number of samples above standard	35	347	1,297	1,323	1,900	1,705	1,971	1,858	1,629	12,065
Number of samples below standard	183	776	922	762	1,181	1,120	1,248	1,378	1,097	8,667
Percentage of adulteration	83.9	69.1	41.7	36.5	38.3	39.6	38.7	42.6	40.2	41.8
Number of samples of drugs examined	603	682	1,007	888	550	862	600	400	424	6,016
Number of samples of good quality	357	431	571	463	400	634	503	325	352	4,036
Number of samples adulterated, as defined by the statutes	246	251	436	425	150	228	97	75	72	1,980
Percentage of adulteration	40.8	36.8	43.3	47.8	27.3	26.4	16.2	18.7	17.0	32.9
Total examinations of food and drugs	1,298	2,644	4,778	4,326	5,420	5,766	5,454	5,985	5,294	40,965
Total examinations of good quality	720	1,210	2,751	2,649	3,563	4,019	3,716	4,096	3,558	26,282
Total examinations not conforming to the statutes	578	1,434	2,027	1,677	1,857	1,747	1,738	1,889	1,736	14,683
Percentage of adulteration	44.5	54.2	42.4	38.7	34.3	30.3	31.9	31.5	32.8	35.8
Expense of collection, examination, and prosecution	$2,931 56	$5,529 60	$8,557 43	$8,025 34	$8,803 62	$8,915 41	$10,356 28	$10,013 04	$10,019 41	$73,151 69
Expense of collection, and examination per sample	2 26	2 09	1 79	1 85	1 62	1 54	1 89	1 67	1 89	1 79

As is customary under the operation of all new laws of similar character, the first few months of work are usually devoted to an examination of the different sorts of food, in order to determine the extent and the character of adulteration. This preliminary examination established the fact that many staple products are not subject to adulteration, except in rare and exceptional instances. This applies, so far as Massachusetts is concerned, to sugar, flour, and the various other cereal products, so that it has not been deemed necessary to give much attention to these articles of food. Hence the figures in the foregoing table should not be understood as representing the actual amount of adulteration existing in the general food-supply, nor even in articles liable to adulteration, since special pains are taken at times to obtain only such articles as are known to be adulterated. Experience often shows an inspector where to find adulterated articles of food. The difference in the percentages of the first two years (1883 and 1884) and the last two (1890 and 1891) in the foregoing table may be taken as representing quite fairly the improvement, not in the general food-supply under the present inspection, but in those articles which are found to be liable to adulteration. Upon this point the Board published the following general statement in its Annual Report of 1884 :

"There can be no question as to the beneficial results of the law, as executed by the officers of the Board, in improving the quality of the food and drug supply of the State, especially in regard to milk and butter—in the former case as relates to the quality of the supply, and in the latter as relating to the proper branding and marking of spurious goods. The extensive correspondence of the Health Department with wholesale houses outside of Massachusetts also confirms their appreciation of the value of the work done in this State, and also the necessity of furnishing articles of undoubted purity for this market. This is especially true of all classes of drugs sold at wholesale by parties outside the State.

"The actual economic results obtained by the enforcement of the statutes relative to food and drug inspection cannot be stated exactly. The law is comprehensive and its provisions cover a great variety of articles. Its restraining influence extends outside of Massachusetts to manufacturers sending goods to this market. Such parties appreciate the value of the work done in this State, and also the necessity of furnishing articles of undoubted purity for this market. It is specially provided by the statute that at least three-fifths of the amount appropriated shall be expended in the enforcement of the laws relating to the adulteration of milk and its products. This provision has been carefully observed."

It was found convenient, after a year's work, to adopt a code of regulations for the government of its analysts and inspectors in the performance of their duties under the Food and Drug Acts. The following is a copy of these regulations. It is not thought necessary to repeat the laws in force in Massachusetts here, since the substance of them has been presented in the third volume of the REFERENCE HANDBOOK :

Rules and Regulations of the State Board of Health of Massachusetts Relative to the Inspection and Analysis of Food and Drugs.—1. The State Board of Health shall appoint analysts and inspectors, as provided in section 5 of chapter 263, Acts of 1882.

2. It shall be the duty of the inspectors to procure samples of drugs and articles of food at such times and places as the secretary shall direct, in the manner provided in section 6 of chapter 263 of the Acts of 1882, and in section 3 of chapter 289 of the Acts of 1884, and in all acts amendatory of said provisions.

3. Under the direction of the secretary, the inspectors shall, for the identification of samples, affix a number to each sample of food or drugs obtained by them, in such manner as may be prescribed. Under no circumstances shall an inspector convey any information to an analyst as to the source from which any sample was obtained.

4. The inspectors shall keep records of each sample, each record to include the following items : (*a*) The inspector's number ; (*b*) the date of purchase or receipt of sample ; (*c*) the character of the sample ; (*d*) the name of the vendor ; (*e*) the name of the city or town, and street and number where the sample is obtained, and in the case of a licensed milk pedler, the number of his license ; (*f*) as far as possible the names of manufacturers, producers, or wholesalers, with marks, brands, or labels stamped or printed upon goods.

5. It shall be the duty of the analysts so appointed to determine, under the direction of the secretary, by proper examination and analysis, whether articles of food and

drugs, manufactured for sale, offered for sale, or sold within this Commonwealth, are adulterated within the meaning of chapter 263 of the Acts and Resolves passed by the General Court of Massachusetts in 1882, and all acts amendatory thereof, adulteration being defined as follows, viz. .

In the case of drugs, (1) If sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein, unless the order calls for an article inferior to such standard, or unless such difference is made known or so appears to the purchaser at the time of such sale. (2) If when sold under or by a name not recognized in the United States Pharmacopœia, but which is found in some other pharmacopœia or standard work on Materia Medica, it differs materially from the standard of strength, quality, or purity laid down in such work. (3) If its strength or purity falls below the professed standard under which it is sold.

In case of food: (1) If any substance or substances have been mixed with it, so as to reduce or lower or injuriously affect its quality or strength. (2) If any inferior or cheaper substance or substances have been substituted wholly or in part for it. (3) If any valuable constituent has been wholly or in part abstracted from it. (4) If it is an imitation of or is sold under the name of another article. (5) If it consists wholly or in part of a diseased, decomposed, putrid, or rotten animal or vegetable substance, whether manufactured or not, or in the case of milk, if it is the produce of a diseased animal. (6) If it is colored, coated, polished, or powdered, whereby damage is concealed, or if it is made to appear of better or of greater value than it really is. (7) If it contains any added poisonous ingredient, or any ingredient which may render it injurious to the health of the person consuming it.

6. It shall also be the duty of the analysts to receive such specimens of food and drugs for analysis as may be delivered to them by the secretary, or by the inspectors, and to examine the same. To avoid, as far as possible, all suggestion or danger of specimens having been tampered with, each analyst shall keep each specimen in his possession in a suitable and secure place, labelled in such a manner as to prevent any person from having access to the same without the knowledge and presence of the analyst.

Analyses of perishable articles should be made promptly after they are received.

7. An analyst shall give no information, under any circumstances, regarding the result of any analysis, to any person except to the secretary of the Board, prior to any trial in court in reference to such analysis.

The analysts shall carefully avoid any error regarding the inspector's number attached to each sample, and shall report the results of their work in detail to the secretary.

In the case of all articles having a numerical standard provided by statute, the result of the analysis should show their relation to such standard.

8. Before beginning the analysis of any sample, the analyst shall reserve a portion, which shall be sealed, and in the event of finding the portion analyzed to be adulterated, he shall preserve the sealed portion, so that in case of a complaint against any person the last-named portion may, on application, be delivered by the secretary to the defendant or to his attorney.

9. Each analyst shall present to the secretary, on the Monday before the first Thursday of each month, a summary of the analyses made by him during the previous month.

Each analyst shall also present, on or before the first of January of each year, an annual report of the work done for the year ending on the 30th of September preceding.

10. The secretary shall have charge of the reports of analyses, and shall cause cases founded on such reports to be submitted to the courts for prosecution.

In each case of a retailer, and of every dealer not a manufacturer or producer, he may, if the party has not been previously complained of in court, issue a notice or warning of any violation of the law relative to the adulteration of food and drugs, and of the offender's liability to prosecution on a repetition of the sale.

11. Should the result obtained by any analyst be questioned in any given case, another analyst shall repeat the analysis, unless otherwise instructed by the Board, provided a sufficient sum to meet the expense of the analysis be deposited with the secretary by any interested party feeling aggrieved, which sum will not be returned unless the second analysis fails to confirm the first in essential particulars.

12. Any appeal from the decision of an analyst shall be filed with the secretary, who shall report it, and any matter in controversy to the Board, giving his judgment thereon, and the Board shall supervise and control the action of its officers in executing the law.

13. Where standards of strength, quality, or purity are not fixed by the act, the analysts shall present to the secretary such standard as in their judgment should be fixed, and the secretary shall report the same to the Board for its action. The standards set by the British Society of Public Analysts will be followed, as nearly as practicable, until otherwise ordered.

14. Whenever a drug or preparation, not prescribed in a national pharmacopœia or other standard work on Materia Medica, shall be manufactured, offered for sale, or used in this State, the standard of such drug, and the standard and proportion of the ingredients of such preparation, and the range of variability from such standard or standards, shall be ascertained by the analysts, who shall report the same through the secretary to the Board.

15. The analysts shall occupy such time in the performance of their respective duties as a reasonable compliance with the terms of the statute shall require, and shall be present one hour of each day, at such time of the day and at such place as shall be designated by the Board, to meet the convenience of interested parties and the public.

The following classified list embraces most of the examinations of articles of food examined in Massachusetts under the Food and Drug Acts up to October 1, 1891:

Articles examined.	Number examined.	Number adulterated or below standard.	Per cent. of adulteration.
Milk	20,732	8,667	41.8
Condensed milk	20	2	10
Butter	1,195	338	28
Cheese	130	1	0.8
Vinegar	1,146	652	57
Lard	173	74	43
Olive-oil	313	206	66
Spices and Condiments:			
Black pepper	997	331	33
White pepper	582	239	41
Cayenne pepper	146	33	23
Mustard	784	379	47
Cloves	737	154	21
Cassia and cinnamon	789	103	13
Pimento	18	2	11
Ginger	663	73	11
Nutmeg	18	1	6
Mace	179	69	39
Allspice	346	27	8
Curry powder	21	0	0
Coffee	296	97	33
Tea	352	5	1
Cocoa and chocolate	72	9	12.5
Wheat flour	22	0	0
Bread	24	1	4
Cake	3	0	0
Corn-meal, rye-meal, oat-meal, barley-meal	15	0	0
Sago, tapioca, and corn-starch	21	0	0
Buckwheat and cerealin	3	0	0
Cream of tartar	1,877	376	20
Baking powders	156	115*	74
Soda and saleratus	100	2	2
Molasses	1,165	212	18
Syrups	39	13	33
Maple syrup	210	89	42
Sugar	151	7	5
Maple sugar	118	44	37

* Containing alum.

Articles examined.	Number examined.	Number adulterated or below standard.	Per cent. of adulteration.
Glucose	4	2	50
Honey	266	118	44
Confectionery	285	52	18
Milk sugar	1	0	1
Pickles	29	2	7
Lime-juice	7	0	0
Lemon-juice	21	21	100
Horse-radish	20	8	40
Arrow-root	21	4	19
Gelatine	34	3	9
Salt	21	1	5
Canned foods †	203	133	66
Flavoring extracts	39	5	13
Sardines	5	4	80
Jellies and jams	61	12	20
Fig paste	2	1	50
Whiskey, wine, ale, beer, and cider ‡	17	7	41
Miscellaneous §	79	0	0
Drugs	6,016	1,980	33

† A considerable portion of these were French vegetables, which were examined for the presence of copper as a coloring agent.

‡ A large number of examinations of spirits and wines is included in the item of drugs.

§ Under this head are included samples of sage, marjoram, macaroni, vermicelli, poultry dressing, desiccated cocoa-nut, citron, compressed yeast, meat-extracts, etc.

A broad view of the subject of food inspection would include the examination of water as one of the necessaries of life, since it is essential to the preparation of most articles of food, and also a convenient vehicle for the administration of very many of them. It is also absolutely necessary to the healthy growth of the human organism.

The important work of water analysis has been conducted by the Engineering Department of the State Board of Health since 1887, and this work has been extended to the examination of the waters of the ponds, streams, springs, reservoirs, and wells used as public supplies by about one hundred and fifty cities and towns in the State. The total number of such examinations has been about ten thousand five hundred. Full reports upon this subject may be found in the reports of the Board for the years 1887 to 1892.

In addition to the regular routine mode of food and drug inspection in Massachusetts, much has been accomplished by work in special directions during the nine years since the work was begun. These may be enumerated as follows:

Investigations relating to the *quality of milk* as produced by the cow.

Analysis of injurious and other empirical preparations: Hair-dyes, cosmetics, bitters, and tonics; alleged cures for the opium and alcohol habits, etc.

Coloring-matters in food: Milk, butter, oleomargarine, preserved vegetables, salts of tin in molasses, etc.

Food Preservatives. — The quality of *wines and liquors;* report upon *oleomargarine;* the uses of *glucose* in food; the presence of *trichinæ* in pork products; the standard of *vinegar; baking-powders;* the use of the word "*compound.*"

The Standard of Milk.—For the purpose of determining the consistency of the existing standard of milk in Massachusetts, analyses were made in 1884 of the milk of six hundred cows, the samples being collected in different parts of the State, and from different herds of animals, of different ages, and in different seasons of the year. The average total solids of the entire number was found to be very nearly thirteen and one-third per cent. (the legal standard is thirteen per cent.). In later years these figures have been confirmed by further examinations upon the same point.

With reference to breeds of cows the results of analyses were as follows:

The average milk of	11	Jerseys	had	14.02	total solids	and	4.34	fat.
"	"	"	"	92	native cows	"	13.09	"	"	"	3.31	"
"	"	"	"	30	Ayrshires	"	12.97	"	"	"	3.35	"
"	"	"	"	51	Durhams	"	12.73	"	"	"	3.28	"
"	"	"	"	47	Holsteins	"	12.51	"	"	"	3.29	"

Artificial Coloring-matter in Food.—The practice of employing coloring-matters in connection with different articles of food is very common. The following may be named as very common examples:

Certain condiments, such as mustard, ginger and other spices, sugar, confectionery, preserved and canned goods (especially peas and beans), milk, butter, oleomargarine, pickles, cake, syrups, and various sorts of beverages.

The coloring-matters employed in connection with these articles of food may be classified as follows:

1. *Harmless Colors.*—These are usually made from some comparatively harmless organic products, such as annatto, caramel, turmeric, and cochineal.

2. *Injurious Colors.*—These are usually some of the metallic compounds, such as lead, copper, and tin.

It cannot be urged in regard to any of these colors, whether harmless or otherwise, that they have any true value as articles of food, and the demand for their use comes mainly from the trader, and not from the actual consumer, excepting, so far as the latter has been erroneously educated by the former as to color-standards in the matter of food. No good and useful end is attained by their use, so far as the question of nutriment is concerned, and not only may harm ensue, but also even fatal consequences, as in recent cases which occurred in Philadelphia from the use of poisonous compounds of lead.

The true use of artificial-food colors is usually a fraudulent one, and they are consequently employed mainly for the purpose of giving to an inferior article of food a fictitious value, and thus to imitate other articles of a similar character, but of better quality, at least so far as their actual cost is concerned. The difference in actual nutritive value as articles of food may, however, be but little or nothing.

When examinations of milk were made in Massachusetts soon after the enactment of the law of 1882, it was found that the addition of coloring-matter to milk was a very common practice in the cities. From the fact that colored samples of milk were almost invariably found to be adulterated in other ways, it was inferred that artificial coloring was practised for the purpose of concealing fraud, and of giving to milk which had been skimmed and watered the appearance of milk of good standard quality. Hence a vigorous warfare was made against the practice until it disappeared.

The question of the sale of preserved vegetables colored bright green by sulphate of copper came to the attention of the Board, and the safe ground was taken that the introduction of poisonous metallic colors in any amount whatever, should have no legitimate place in the food-supply of the people.

Trichinæ in Pork.—Among the many questions relating to the food-supply in Massachusetts the quality of the pork offered for sale has not been overlooked. Nearly thirteen thousand hogs have been examined under the direction of the Board for the presence of trichinæ. Of this number seven hundred and ninety-one, or 6.3 per cent., were found to be trichinous. Western hogs were found to contain less than Eastern, and of those raised in Massachusetts, those reared in public institutions and upon the refuse of cities were found to suffer the most. An examination was also made of sausages, and only one out of 365 was found to contain trichinæ.

Baking-powders. — No class of substances employed in the preparation of food has been the subject of so much discussion as these; and this is true notwithstanding the fact that, as elements in the matter of food economy, or as nutritive constituents of the necessary food of mankind, they have absolutely no value. Their use in the preparation of food was unknown until the early part of the present century, and for ages the human race has thrived without them. Whenever bread was desired which should possess the properties of porosity and lightness of texture, in early times, some sort of leaven or yeast was employed for the purpose.

The use of baking-powders at the present day is due, undoubtedly, to several causes, prominent among which is a demand for rapid and convenient methods of pre-

paring bread and pastry for cooking; and, also, to the stimulus of trade produced by excessive advertising.

If the statements of rival manufacturers as to the poisonous qualities of all other baking-powders except their own were to be credited, the use of these preparations would soon cease. Such false teaching does harm in misleading the community and creating a distrust. The fallacy lies in the want of discrimination between large and small doses of the ingredients of such powders. For example, common salt and mustard act as poisons in large doses and produce vomiting. In small doses, on the contrary, neither of them is harmful.

The same is also true, to a certain extent, of cream of tartar, alum, and other ingredients of baking-powders. Another property which is common to this class of articles is that of chemical reaction, which takes place when the different ingredients of these powders are brought in contact, and also into solution, in the process of preparation of bread. The resulting salts which follow this union may, and often do, have very different properties from those which were characteristic of the different ingredients of which such powders were originally composed. In one instance hydrate of alumina is the resulting salt; in another, a salt quite similar to Rochelle salts; and in another, the phosphate of alumina. It is therefore a misleading statement to call alum "a corrosive poison," or to assert the same property of cream of tartar or the acid phosphate of lime, since it is not in either of these forms that the baking-powder is ingested by the consumer. For the same reason it is also manifestly wrong to state that cream of tartar or phosphate of lime is healthful. Both of these are drugs, and as such have their proper uses. Their constant daily use is another question.

The singular claim has been made in behalf of the phosphate of lime that it "restores the phosphates lost by the removal of the bran." It may reasonably be asked whether, in the interest of public health, as well as economy, it would not be better to retain this valuable portion of the grain in preference to the attempt to substitute for the natural constituent an artificial representative. Flour made from the whole wheat, or other grains, while it may be less pleasing to the eye and possibly to the taste, has the advantage of producing wholesome bread.

Claims are made by the makers of baking-powders of purity for their own products, and also of impurity for the products of others. In whatever sense these terms may be regarded by the community at large, it should be remembered that the introduction of these articles is of comparatively recent date; that they are compounded of several ingredients; that different manufacturers employ different ingredients to attain the same object or end. No standard has ever been adopted by any government authority, so far as we can learn, for this class of preparations; hence the use of the terms *purity* and *impurity*, as applied to them, must be considered as arbitrary, or at least merely conventional. Experiments have been undertaken with the view of settling the question as to whether the ingredients of certain baking-powders were injurious to health; and, while positively harmful results have in some instances been reached by the ingestion of considerable doses of such ingredients, when taken singly, still, the question of actual injury to health, on the one hand, or of freedom from harm on the other, from the use of baking-powders in food, cannot be regarded as settled.

Mixtures or Compounds.—The work of inspection includes a careful examination of the methods in which food is offered for sale, especially with reference to the question of labelling and the agreement of the label with the actual contents of the package to which it is affixed, since the statute of Massachusetts provides that "mixtures or compounds" are not to be treated as adulterated in the eye of the law, "provided that the same are not injurious to health and are distinctly labelled as mixtures or compounds."

This provision of the law is frequently disregarded, especially in the case of spices; and while the term "compound" is to be found after prolonged search upon the label, it often occupies an obscure position, or is printed in extremely small type, so that the term "*distinctly* labelled" does not apply.

It is not always safe to infer that all parts or packages in a lot of spices or similar articles of food are pure, because a single sample or package proves to be pure. The following case is an illustration: Two packages of powdered cloves were obtained at a grocery. The packages were in unbroken tin boxes of one-quarter pound each, and were purchased at an interval of three weeks; each package was of the same size, and each had exactly the same brand or label. On inquiry of the retailer it was found that both of the packages came from the same lot. It appeared on examination that the first package was considerably adulterated and the second was pure. A notice of this fact was therefore sent as usual to the retailer, who transmitted the notice to the manufacturer, who lives outside the limits of the State; he denied the charge, and hence, as is customary in cases of disputed analysis, samples were sent to a second analyst, who confirmed the statement of the first; and finally, four analyses were made with the same result, neither chemist knowing anything of the source of the samples, nor did either know that a previous analysis had been made.

This circumstance shows that it is not always safe to judge of the character of any group or lot of articles from the examination of a single sample.

Gross Appearances.—It is evident that very little reliance can be placed upon the mere external inspection of articles of food, such as may be made by the employment of the senses of taste, touch, smell, and sight, since the principal object of the falsifier of food preparations is to deceive the senses of the consumer by every possible resource of his art. It is a common experience in this department of work to receive articles of food from various sources, which are believed by the persons presenting them for examination to be adulterated, but which the analyst finds to be pure. This experience is true in the case of many of the articles of food which are liable to adulteration, and also of some articles which are scarcely ever found to be adulterated. The same experience has been met by other authorities who have had charge of similar work ("Report of Commissioner of Internal Revenue, Washington, 1887," p. cxliii.). Among the various articles which have been thus submitted to the Board for examination (under the impression of the person submitting them that they were adulterated) were the following: Flour, sugar, molasses, vinegar, cream of tartar, honey, milk, butter, cheese, lard, salt, and several kinds of spices or condiments.

The reasons for these false notions with reference to the quality of articles of food are mainly the following: 1. A liability to mistake the deterioration of an article, or an inferiority in grade or quality, for an actual falsification or substitution. 2. A lack of familiarity with the true physical characteristics of the article in question.

Notices to Retailers.—It has been the custom of the Board to issue a warning notice to retailers selling articles found to be adulterated, in cases where there was a reasonable probability that the retailer was not aware that such articles were adulterated.

In certain articles of food which have been specially liable to fraud, such as the various sorts of spices, condiments, cream of tartar, etc., adulteration has been greatly diminished, and is in many instances limited to parties whose business is conducted outside of the State, and cannot therefore be easily reached except through the customary notice sent to the retailer who buys of such outside parties.

These notices have proved to be a very efficient mode of diminishing adulteration. It is not the retailer who is seriously affected by the receipt of such a notice, but the wholesale dealer or manufacturer to whom it is speedily forwarded by the retailer, and who finds that he cannot afford to continue a wholesale imposition.

Drugs.—The term "drugs" in the Massachusetts Act of 1882 embraces "all medicines for internal and external use, antiseptics, disinfectants, and cosmetics.

Hence the work of the State Board of Health, in this direction, has not been confined to the remedies defined in the United States Pharmacopœia, but has embraced many other articles, and especially empirical preparations of a more or less harmful character.

Of the drugs found to be of a specially inferior quality during the earlier investigations of the analysts in 1883 and 1884 were the following:

Tincture of opium (U. S. P., 1.20 to 1.60 parts per 100 of morphine), 144 samples out of 197 fell below the required limit of 1.2, and some had as little as .01, .14, .17, or a mere fraction only of the minimum requirement. Citrate of iron and quinine (legal requirement twelve per cent. of quinine), eighty-five per cent. of the samples had less than the required amount, and several had as little as three and 3.5 per cent., or but little more than a quarter of the requirement. Of powdered jalap only one sample out of twelve conformed to the pharmacopœial standard. Of 192 samples of powdered drugs, 39 were found to be adulterated in various forms. Of 19 samples of compound spirits of ether, 2 only contained the required amount of the ethereal oil required by the statutes. Of 23 samples of spirit of nitrous ether, scarcely any had the required amount of ethyl nitrite.

Twenty-two samples or lots of the quinine pills made by different manufacturers were examined. These were examined in two groups, at an interval of several months, during which time the manufacturers had become aware of the work of the Board in this direction. The analysis of the second group showed in nearly every instance an improvement. The following figures indicate the percentages of the required weight of the pills made by nine manufacturers, in the two series of analyses:

First Series.	Second Series.	First Series.	Second Series.
1. 93.5	97.9	6. 84.7	89.5
2. 86.6	97.3	7. 93.8	101.1
3. 93.3	99.6	8. 104.4	100.5
4. 93.8	100.7	9. 97.0	97.1
5. 107.6	76.5		

The foregoing list shows an improvement in each case except two. Of 106 samples of pharmacopœial spirits and wines, only 10, or 9.4 per cent., conformed to the legal requirements.

In proof of the improvement under the action of the statutes, very marked changes for the better have been found to have taken place in many of the foregoing articles.

Among the non-pharmacopœial preparations examined in 1885, were eleven hair-dyes, all of which contained lead in large amounts; also twenty different fraudulent nostrums advertised for the cure of the opium-habit, most of which were solutions of morphine. One of them was the so-called "Keeley gold cure," which was found to contain no gold whatever. In 1887 about fifty proprietary articles, sold as tonics and bitters (some of which were advocated as temperance drinks), were examined chiefly for their alcoholic contents. All were found to contain alcohol in the proportion of six to forty-eight per cent. by volume. One of these, which was advertised as a remedy for inebriety and the opium-habit, was the celebrated "Scotch Oats Essence," containing alcohol and morphine, the latter in varying proportions. This nostrum very soon disappeared after its analysis had been published.

Cosmetics for the complexion, termed face-bleaches, freckle-lotions, skin-tonics, have been examined and found to consist of strong solutions of corrosive sublimate. It was required that these, if sold at all, should be labelled as poisons, and sold under careful restrictions only. Seventeen complaints were made against parties selling these articles in violation of the statutes.

In the following brief table the ratio of adulteration found in articles of food and drugs in England and in Massachusetts, during the period of inspection and enforcement of the laws, is presented:

PERCENTAGE OF ADULTERATION AS GIVEN IN THE REPORTS OF EACH YEAR.

Year.	England and Wales. Ratio of adulteration. Per cent.	Average 5 years. Per cent.	Massachusetts. Ratio of adulteration. Per cent.
1877	19.2		....
1878	17.2		....
1879	14.8	....16.2	....
1880	15.7		....
1881	14.7		....
1882	15.1		....
1883	15.0		44.5
1884	14.4	.....13.9	54.2
1885	13.2		42.4
1886	11.9		38.7
1887	12.8		34.3
1888	10.8		30.3
1889	11.5	.....12.7	31.9
1890	11.2		31.5
1891	12.2		32.8

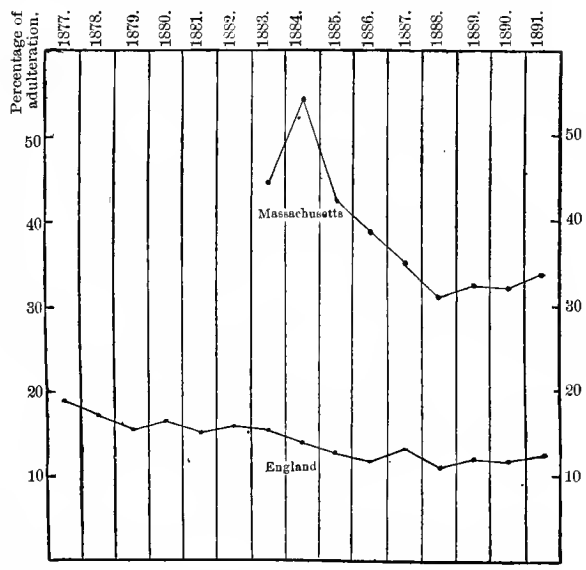

FIG. 160.—Diagram showing the Ratio of Adulteration in England, 1877–91, and in Massachusetts, 1883–91.

As a comment upon the foregoing table and diagram the following observations may be made:

First. The gradual lessening of adulteration under the action of judicious legislation.

Second. The much greater ratio presented in the column headed Massachusetts than in that of England and Wales.

The reason for this great difference may be found, *first*, in the fact that in conformity to the requirements of the statutes in Massachusetts more than half the samples examined were milk. The standard of milk in the State is unusually high as compared with that of other countries (thirteen per cent. of solids, except in May and June, when it is twelve per cent.). Hence it is the custom to report all samples as adulterated which are found to be below the foregoing limits. Now, there are many animals, especially those of the Holstein breed, which habitually produce milk having less than thirteen per cent. of solids. Hence it has not been deemed prudent to enter complaints at court to the full extent of the legal requirements. In the case of milk, therefore, the ratio of adulteration as reported is partially an apparent and not an actual adulteration. *Secondly*, the samples selected under the Massachusetts law are mainly such as are known or suspected to be adulterated, while in England many samples of such staple articles as bread, flour, sugar, and tea are annually examined, which are practically free from adulteration.

In the following table and diagram the articles exam-

ined are classified in three groups, by means of which this element of apparent adulteration in milk is separated:

PERCENTAGE OF ADULTERATION IN MILK, OTHER ARTICLES OF FOOD, AND DRUGS IN MASSACHUSETTS.

Years.	Milk.	Other articles of food.	Drugs.
1883	83.9	35.4	40.8
1884	69.1	48.5	36.8
1885	41.7	43.1	43.3
1886	36.5	36.2	47.8
1887	38.3	29.4	27.3
1888	39.6	19.2	26.4
1889	38.7	24.0	16.2
1890	42.6	18.6	18.7
1891	40.2	26.4	17.0

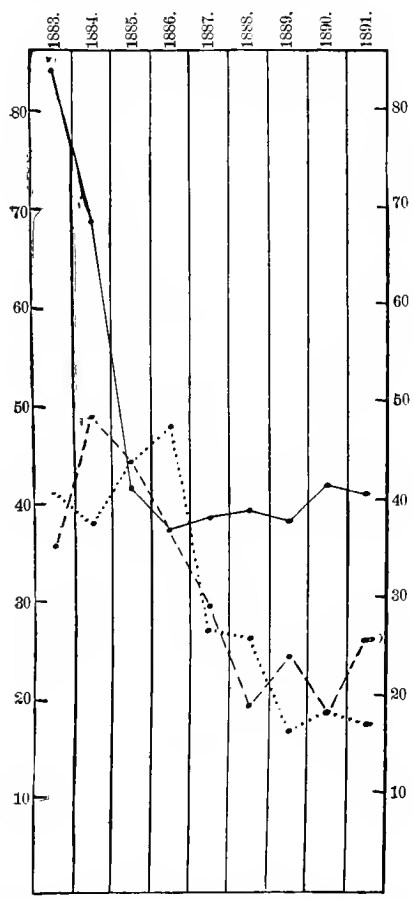

FIG. 161.—Diagram showing the Ratio of Adulteration of Drugs and Different Articles of Food in Massachusetts in the Years 1883-91. Milk, ——; other articles of food, – – –; drugs, ...

The ratio of samples of food collected for examination to the whole population for the past five years has been about as follows: In England and Wales, 1 to each 1,000 of the population; in the city of Paris, 1 to each 120 of the population; in Massachusetts, 1 to each 375 of the population.

The work of a food analyst embraces a variety of branches. In a recent monograph by two French army surgeons, Polin and Labit, the following classification of such work is presented. Three principal groups, as follows: 1. Examination of articles in which the alterations in character are either of a chemical or of a mechanical kind. 2. Those which are biological. 3. Those which are parasitic.

The first group is subject to the following subdivision. (*a*) Additions have been made to the food products either of a commercial or fraudulent nature, and of substances more or less harmful. (*b*) The vessel in which the food has been prepared or preserved renders the food poisonous. (*c*) The manipulation of food, or its surroundings, may expose it to harmful contamination. (*d*) It may be mixed accidentally with foreign substances.

The second group is subject to the following divisions: (*a*) An animal designed for food has been fed with food of a harmful or poisonous character; the poisons absorbed appear in the milk, or, not having had time to become eliminated, either the whole animal or some of its organs have become poisonous. (*b*) Recognizes the possibility of the formation of poisonous ptomaines in meat, under certain conditions. (*c*) In consequence of certain unknown conditions wholesome vegetable food occasionally becomes harmful.

Third group: (*a*) Animal, vegetable, and mineral food products may be invaded by parasites of the larger kinds. (*b*) Food may become the prey of micro-organisms of a parasitic nature, involving the processes of (1) fermentation, (2) putrefaction and (3) the development of infectious diseases, either of which may render the food harmful, either by infection, by ptomaïne poisoning or by the combined action of both. (*c*) Food contaminated by its surroundings, or by infectious contact, becomes the carrier of pathogenic germs.

This list is sufficiently ample to show that the food analyst has a wide field of investigation.

The following special regulations regarding food inspection were published by Dr. Schumacher Kopp, Canton Chemist of Lucerne, and also a member of the International Jury of Award at the Paris Exposition of 1889.

The following extract is taken from his report:

Collection of Food.—In collecting food the greatest cleanliness should be observed. Clean bottles, and, if possible, new ones, should be used in collecting fluids. Bottles should be closed only with new corks.

In collecting drinks, the local experts must be present, and the beverages should be drawn from the regular source of supply.

In collecting milk, fill the bottle to the cork; seal every bottle at once after corking it. If milk is collected in a stable, the cows must be milked quite dry, by a disinterested person, and in the presence of the local magistrate, or a policeman.

Strong glass, or porcelain, or crockery vessels should be used for the collection of butter.

For coffee, tea, and meal, boxes of clean wood or pasteboard should be used.

The use of paper bags for collecting samples is forbidden.

Bread and sausages should be wrapped in clean white paper; if possible, parchment paper.

The use of printed or colored paper for this purpose is forbidden.

Quantity of Food Necessary for Examination.—1. For the local health authority: Beer, one litre; bread, one whole loaf; brandy, 0.3 litre; butter, 50 grammes; vinegar, 0.2 litre; coffee, 30 grammes; meal, 200 grammes; milk, 0.5 litre; cider, 0.5 litre; tea, 10 grammes; drinking-water, 1 litre; wine, 0.5 litre; small sausages, one whole sausage; large sausages, 100 grammes; honey, 50 grammes.

For the Canton Chemist the quantities are nearly the same as the foregoing, but in most instances two samples are taken. When two samples are taken, for example, of water, two litres in one bottle are not meant, but two bottles each containing one litre.

Sealing.—The samples collected must be sealed at once upon the spot, with an official seal. This seal must cover the whole head of the bottle, in order to keep the air out, and to avoid leakage.

Marking.—The samples should be plainly marked in two different places immediately after collection, one on the neck of the bottle, and the other on the opposite side of the body of the bottle. Each marking must contain: 1, The number and name of the article collected; 2,

name of the jurisdiction authorizing the collection, and of the collector.

Provision is made for the collection of two samples when necessary, so that, in case of a dispute, the second may be examined under the auspices of a superior authority. The samples sent to the Canton chemist must contain no information as to their source. A report must also be sent to the Health Officer, stating the articles collected, the date of their collection, name of the dealer, his source of supply, and in every case his remarks upon the character of his goods. This report must be signed by the local expert and by the police assisting in the collection. All samples sent to the Canton chemist must be so packed with sawdust, paper, or wadding, that they may be transmitted without injury. The name of the sender must accompany all packages, letters, etc., and they must be prepaid; otherwise they will not be received.

In sending milk to the Canton chemist, observe especially: 1. That the milk is thoroughly cooled in cold water before it is forwarded. 2. (*a*) In the accompanying report mention must be made first of the number of cows from which a sample of mixed milk is taken; (*b*) how many cows, if any, are in the stable which have calved within fourteen days of collection of the milk; (*c*) how many cows, if any, are near the time of calving.

Food Standards.—*Bread.*—The water in a freshly baked loaf of bread should not be more than thirty per cent. of its weight, and the ash, after deducting the common salt, should not be more than one per cent.

Butter.—This name should only be associated with the fat which is made from milk only. Artificial butter must be properly marked as such, being designated as margarine, and packed in separate parcels. Such names as "cheap butter," "tub butter," and "Alpine butter," are forbidden, except as applied to pure butter.

Vinegar must contain four per cent. of acetic acid. The addition of other acids, flavoring matter, and aniline colors, is forbidden.

Honey must be called honey only when it is free from adulteration. Such terms as "table honey," "Swiss honey," and "Appenzell honey," etc., are forbidden, except when applied to pure honey. Substitutes for honey, such as syrups, etc., and also mixtures of these with pure honey, must be plainly marked as such.

Coffee must not yield more than four per cent. of ash (Mocha, eight per cent.). Artificial coloring is to be regarded as adulteration. Mixtures of coffee with other substances are not to be called coffee.

Rye-meal should not yield more than two per cent. of ash.

Wheat meal should not yield more than one and a half per cent. of ash. The water of rye- and wheat-meal should not be more than fifteen per cent. of its weight, and that of other meals eighteen per cent.

Milk.—Milk must be sold as drawn from the cow. Its specific gravity at a temperature of 15° C. (60° F.) before skimming should not be less than 1.029 nor more than 1.033, and when skimmed after twenty-four hours it should not be less than 1.033 nor more than 1.037. The chemical examination should show at least 11.5 per cent. of solid residue, and at least three per cent. of fat.* When taking milk at dairies for comparison, it is desirable to have examinations made within the shortest possible time, three days at the longest, and the cows should be milked dry by disinterested persons. "Centrifugal" milk should be marked as such, and when inspected at a temperature of 15° C. should have a specific gravity of from 1.034 to 1.037, and should have at least 8.4 per cent. of solids. The sale of the milk of sick cows is forbidden, as well as that of cows within eight days before and after the time of calving.

Cider, after fermentation, must not have less than three per cent. by weight, and 3.76 per cent. by volume of alcohol, and not less than 1.5 per cent. of solids, nor less than .15 of one per cent. of ash.

Tea must not have more than seven per cent. of ash.

Water for domestic use must neither have color nor sediment. Nor should it have smell or bad taste. Water containing infusoria and bacteria should be avoided.

Sausages should be made only of healthy, fresh meat, fat, and spices in general use. Any additions of starches are considered as adulterants.

Propriety of International Laws on the Subject of Food Inspection.—Dr. Von Hamel Ross expressed his opinion, at the International Congress of Hygiene at London, in 1891, that a *codex alimentarius* should be adopted for civilized nations, as agreed upon by a competent commission for general use. He commented upon the different standards of different countries, and as an example quoted the milk standard of Massachusetts, which is thirteen per cent. of solids (twelve per cent. in May and June), while milk having 11.5 per cent. solids is deemed to be pure in Holland.

At the International Congress of Agriculture at The Hague, in the following month (September, 1891), conclusions were formulated as to the need of uniform laws relative to food adulteration and the protection of food products. It was then voted "that each State should establish a commission of competent men, who should be charged with the duty of investigating the methods of analysis in use, and of determining the proper methods of such analysis, and that each State should publish an annual report of its proceedings and exchange reports with other States."

United States.—Recent attempts have been made to secure national legislation for the general prevention of food and drug adulteration in the United States, but thus far the only articles which have become the subjects of such legislation are butter and lard.

The following bill, usually known as the Paddock Bill, was reported to Congress in 1890, and in many respects resembles that which was reported in 1880. Its provisions are reasonable, and not as stringent as those which are in force in some of the States, since knowledge of the fact of adulteration on the part of the vendor must first be proven to secure conviction under this Act.

A Bill for Preventing Adulteration and Misbranding of Food and Drugs, and for other Purposes.—Be it enacted, etc. Section 1. That, for the purpose of protecting the commerce in food-products and drugs between the several States and Territories of this Union and foreign countries, the Secretary of Agriculture shall organize in the Department of Agriculture a division to be known as the food division, and make necessary rules governing the same to carry out the provisions of this act, and appoint a chief thereof, at a salary of $3,000 per annum, whose duty it shall be to procure from time to time, under rules and regulations to be prescribed by the Secretary of Agriculture, and cause to be analyzed or examined samples of food and drugs sold or offered for sale in any State or Territory other than where manufactured. The Secretary of Agriculture is hereby authorized to employ such chemists, inspectors, clerks, laborers, and other employees as may be necessary to carry out the provisions of this act.

Sec. 2. That the introduction into any State or Territory from any other State or Territory or foreign country of any article of food or drugs which is adulterated within the meaning of this Act is hereby prohibited, and any person who shall wilfully and knowingly ship, or deliver for shipment, from any State or Territory or foreign country, to any State or Territory, or who shall knowingly receive in any State or Territory from any other State or Territory or foreign country, or who, having so received, shall deliver, for pay or otherwise, or offer to deliver to any other person, any such article so adulterated within the meaning of this Act, shall be guilty of a misdemeanor, and for such offence be fined not exceeding $200 for the first offence, and for each subsequent offence not exceeding $300, or be imprisoned not

* The standard of whole milk in Paris is a minimum of 11.5 per cent. of solids and 2.7 fat. That of the British Society of Public Analysts is 11.5 total solids and 2.5 fat. That of the State of New York is 12 per cent. of solids and 3 per cent. of fat. Of New Jersey 12 per cent. of solids. Of Massachusetts and New Hampshire, 13 per cent. of solids.

exceeding one year, or both, in the discretion of the court.

Sec. 3. That the chief of said food division shall make, or cause to be made, under rules and regulations to be prescribed by the Secretary of Agriculture, examinations of specimens of food and drugs which may be collected from time to time, under rules and regulations to be prescribed by the Secretary of Agriculture under its direction in various parts of the country, and publish in bulletins the result of such analyses. But the names of manufacturers or vendors of such foods or drugs analyzed shall in no case be published in such bulletins until after conviction in the courts of violation of this Act. If it shall appear from such examination that any other provisions of this Act have been violated, the Secretary of Agriculture shall at once cause a report of the fact to be made to the proper United States District Attorney, with a copy of the results of the analysis duly authenticated by the analyst under oath.

Sec. 4. That it shall be the duty of every district attorney to whom the food division shall report any violation of this Act to cause proceedings to be commenced and prosecuted without delay for the fines and penalties in such case provided, unless, upon inquiry and examination, he shall decide that such proceedings cannot probably be sustained, in which case he shall report the facts to the food division.

Sec. 5. That the term "drug," as used in this Act, shall include all medicines for internal or external use. The term "food," as used herein, shall include all articles used for food or drink by man, whether simple, mixed, or compound.

Sec. 6. That for the purposes of this Act an article shall be deemed to be adulterated—

In case of drugs :

First. If, when sold under or by a name recognized in the United States Pharmacopœia, it differs within the knowledge of the seller from the standard of strength, quality, or purity according, to the tests laid down therein.

Second. If, when sold under or by a name not recognized in the United States Pharmacopœia, but which is found in some other pharmacopœia or other standard work on materia medica, it differs within the knowledge of the seller materially from the standard of strength, quality, or purity, according to the tests laid down in said work.

Third. If its strength or purity fall below the professed standard under which it is sold.

In the case of food or drink :

First. If any substance or substances has or have been knowingly mixed and packed with it so as to reduce or lower or injuriously affect its quality or strength, so that such product, when offered for sale, shall be calculated and shall tend to deceive the purchaser.

Second. If any inferior substance or substances has or have been knowingly substituted wholly or in part for the article, so that the product, when sold, shall be calculated and shall tend to deceive the purchaser.

Third. If any valuable constituent of the article has been knowingly wholly or in part abstracted, so that the product, when sold, shall be calculated and shall tend to deceive the purchaser.

Fourth. If it be an imitation of and knowingly sold under the specific name of another article.

Fifth. If it be knowingly mixed, colored, powdered, or stained in a manner whereby damage is concealed, so that such product, when sold, shall be calculated to deceive the purchaser.

Sixth. If it contain within the knowledge of the seller any added poisonous ingredient or any ingredient which may render such article injurious to the health of the person consuming it.

Seventh. If it consist within the knowledge of the seller of the whole or any part of a diseased, filthy, decomposed, or putrid animal or vegetable substance, or any portion of an animal unfit for food, whether manufactured or not, or if it is the product of a diseased animal, or of an animal that has died otherwise than by slaughter : *Provided*, That an article of food or drug which does not contain within the knowledge of the seller any added poisonous ingredient shall not be deemed to be adulterated—

First, in the case of mixtures or compounds which may be now or from time to time hereafter known as articles of food under their own distinctive names, and not included in definition fourth of this section ;

Second, in the case of articles labelled, branded, or tagged so as to plainly indicate that they are mixtures, compounds, combinations or blends ;

Third, when any matter or ingredient has been added to the food or drug because the same is required for the production or preparation thereof as an article of commerce in a state fit for carriage or consumption, and not fraudulently to increase the bulk, weight, or measure of the food or drug, or conceal the inferior quality thereof ;

Fourth, where the food or drug is unavoidably mixed with some extraneous matter in the process of collection or preparation.

Sec. 7. That every person manufacturing, offering, or exposing for sale, or delivering to a purchaser any drug or article of food included in the provisions of this Act shall furnish such drugs or article of food to any person interested or demanding the same, who shall apply to him for the purpose, and shall tender him its value, of a sample sufficient for the analysis of any such article of food which is in his possession. And upon the presentation of such drug or article of food to the proper officer of the food division by a responsible person, with a request from such person for an official analysis of the same, the chief of such division shall make, or cause to be made, such analysis of the drug or article of food so presented, under rules and regulations to be prescribed by the Secretary of Agriculture.

Sec. 8. That whoever refuses to comply, upon demand, with the requirements of section seven of this Act shall be guilty of a misdemeanor, and, upon conviction, shall be fined not exceeding $100 nor less than $10, or imprisoned not exceeding one hundred nor less than thirty days, or both. And any person found guilty of manufacturing, offering for sale, or selling an adulterated article of food or drug under the provisions of this Act shall be adjudged to pay, in addition to the penalties heretofore provided, for all the necessary costs and expenses incurred in inspecting and analyzing such adulterated articles of which said person may have been found guilty of manufacturing, selling, or offering for sale.

Sec. 9. That in prosecutions for violations of this Act proof of the act done shall be held to imply knowledge and intent on the part of the accused, unless such knowledge and intent shall be disproved on the trial.

Sec. 10. That this Act shall not be construed to interfere with commerce wholly internal in any State, nor with the exercise of their police powers by the several States.

The English Food and Drug Act was quoted with sufficient fulness in the third volume of the REFERENCE HANDBOOK ; hence it is not repeated here.

Germany.—After the enactment of the English law, a demand arose in Germany for similar legislation, and a bill was introduced early in 1879, which became a law in May of that year.

A very complete inquiry had already been made, in anticipation of this Act, in the year 1878, embracing the examination of 231,478 samples of food, drink, and other articles coming under the proposed law. Of these, 3,508 proved to be adulterated, or 1.5 per cent. only ; 1,538 articles of food were decomposed and unfit for consumption, and 3,332 convictions of offenders were secured. Of the whole number, there were 152,043 samples of milk ; 17,628 of beer ; 21,380 of sausages and meat ; 17,203 of flour and bread, etc. A few glaring instances of the use of harmful ingredients were detected.

The following is the text of the Act in question :

Section 1. The sale of food and articles of consumption, as well as the trade in toys, paper-hangings, colors, eating, drinking, and cooking utensils, and petroleum, is to be regulated by this Act.

Sec. 2. The officers of the sanitary police are empowered to enter any rooms in which the articles coming under Section 1 are kept for sale, during the usual business honrs, or while the rooms are kept open for sale.

They are authorized to take, according to their choice, for the purpose of analysis, samples of the articles coming under Section 1, and which are kept in the sale-rooms, or which are sold in public places, upon market-places, squares, streets, or which are hawked about. If requested, part of the sample must be left with the vendor, properly secured or sealed. For the sample the usnal price is to be paid to the seller.

Sec. 3. The sanitary officers are empowered to make inspections of the premises of persons who have, according to Sections 10, 12, 13 of this Act, been sentenced to imprisonment, or of rooms in which articles specified in Section 1 are kept for sale, or in which such articles intended for sale are stored.

This power of inspection begins with the date at which the sentence takes force, and ceases after three years from the date on which the term of imprisonment ceases, or is remitted.

Sec. 4. Sanitary officers, in the meaning of this Act, are the medical sanitary officers, as well as those officers which are nominated as such by the Superior Court of Administration. The central authority of the empire will decide which court has to act as Superior Court of Administration.

Sec. 5. By imperial decree, with assent of the Federal Council, regulations for the protection of health may be framed to prohibit: 1. Certain modes of preparing, storing, or packing articles of food or consumption intended for sale. 2. The trade and offering for sale of articles of food or consumption, of certain conditions, or under a name not corresponding to their real condition. 3. The sale and offering for sale for slaughter of animals suffering from certain diseases, as well as the sale and offering for sale of the flesh of animals which are affected with certain diseases. 4. The use of certain substances and colors for the manufacture of wearing apparel, toys, paper-hangings, eating, drinking, and cooking utensils, as well as the sale and offering for sale of articles manufactnred contrary to this regulation. 5. The sale and offering for sale of petroleum of a certain nature.

Sec. 6. By imperial decree, with assent of the Federal Council, the manufacture, sale, or offering for sale, of articles intended for adulterating articles of food or consumption may be prohibited or limited.

Sec. 7. The imperial decrees, issued under Section 6, are to be laid before the next following session of Parliament. They are to be put out of force as soon as Parliament so requires it.

Sec. 8. Whoever acts contrary to the regulations of Sections 5, 6, is punishable with a fine up to 150 marks (about $35), or with imprisonment.

Sec. 9. Whoever, contrary to regulations of Sections 2 to 4, refuses entry to the rooms, the taking of samples, or inspection, is punishable with a fine from 50 to 150 marks, or with imprisonment.

Sec. 10. Liable to imprisonment up to six months, and to a fine up to 1,500 marks, or to either of these, is: 1. Whoever, for the pnrpose of fraud in commerce, imitates articles of food or consumption, or adulterates the same by deteriorating them by the subtraction or addition of substances, or gives them the appearance of a better quality. 2. Whoever knowingly sells articles of food or consumption, which are spoiled or imitated, or adulterated according to Section 1, without giving notice of these circumstances, or offers them for sale under a name liable to lead to deception.

Sec. 11. If offences mentioned in Section 10 have been committed by negligence, a fine up to 150 marks or imprisonment is to be inflicted.

Sec. 12. Liable to imprisonment, and to loss of civil rights, is: 1. Whoever prepares articles intended for the food of others in such a manner that their consumption is calculated to injnre health, also, who knowingly sells, offers for sale, or otherwise brings into circulation as articles of food or consumption such articles which are injurious to health. 2. Whoever intentionally manufactures wearing apparel, toys, paper-hangings, eating, drinking, and cooking utensils, or petroleum, so that the probable use of these articles proves injurions to health; also, who knowingly sells such articles, offers them for sale, or otherwise brings them into circulation.

The attempt is pnnishable—

If, through the action, grievous bodily injury, or the death of any person has been caused, penal servitude np to five years is to be inflicted.

Sec. 13. If, in the cases of Section 12, the consnmption or use of the articles was liable to destroy health, and if that circumstance was known to the vendor or manufacturer, penal servitnde up to ten years, or, if the death of any person was caused, penal servitude not under ten years, or for life, is to be adjndged. Besides the punishment, supervision by the police may be ordered.

Sec. 14. If any of the actions indicated in Sections 12 and 13 has been committed through negligence, a fine up to 1,000 marks is to be imposed, or imprisonment up to six months; and if, by the action, the health of any person shall have been injured, imprisonment up to one year; but if the death of any person shall have been caused, imprisonment from one month to three years.

Sec. 15. In the cases of Sections 12 and 14, besides the punishment, the confiscation of the articles which were made, sold, offered for sale, or otherwise brought into circulation, is to be caused, no matter whether the articles belong to the defendant or not; in the cases of Sections 8, 10, and 11, the confiscation may be caused.

If in cases of Sections 12 and 14 the prosecntion or punishment of any person is not practicable, confiscation of the articles alone may be caused.

Sec. 16. In the judgment it may be ordered that the sentence be made public, at the expense of the defendant.

On the motion of any defendant who has been found not guilty, the Conrt has to order the publication of the acquittal; the costs to be paid by the State, unless they are to be paid by the prosecutor.

In the order the mode of publication is to be stated.

Sec. 17. If, for the place where the offence was committed, a public institntion for the examination of articles of food or consumption be in existence, the fines imposed by authority of this law, and as far as the State can dispose of them, go to the fund which provides the cost of maintaining that institntion.

BIBLIOGRAPHY.

FRIEDRICHRODA. A popular watering-place and climatic resort in Thuringia, Germany.

LOCATION.—Friedrichroda is charmingly situated in the "*Thüringerwald*," near the city of Gotha, and at an elevation of 1,300 feet above sea-level. The pure mountain-air, the attractive scenery, the saline waters, and facilities for brine, pine-needle, and other baths all contribute to make it a favorite resort in that section of the country.

ACCESS.—The place is now a station on the railroad running from Gotha to Eisenach.

INDICATIONS.—Friedrichroda is much frequented during the summer season (May to October) by those af-

flicted with minor neuroses, anæmia, bronchial and slight pulmonary affections, and scrofula. There are several bathing establishments, with facilities for massage, hydrotherapy, inhalations, etc. The place is also made use of as "*Terrainkurort*," for the Oertel system. Milk and whey cures are much employed there.

ACCOMMODATION. — There are hotels and numerous boarding-houses; also a *Kurhaus* where music and the usual entertainments are provided.

Edmund C. Wendt.

FRONTAL SINUSES, DISEASES AND INJURIES OF THE. OSTEOMA OF THE FRONTAL SINUS.—The statistics of operations for the removal of these growths continue to show a very high mortality. Thus out of fifty-four cases in which interference to the extent of the removal of the bone was carried out, thirty-three per cent. died of meningitis.[1] The serious nature of the operative procedure seems to be in direct proportion to the size of the tumor. Hence it is suggested that early interference should be practised.[2]

EMPYEMA OF THE FRONTAL SINUSES.—Intense catarrhal inflammation of the frontal sinus may give rise to an empyema of the cavity. This may be due to a primary inflammation, in which an acute or chronic obstruction of the infundibulum occurs, and consequent retention of pus. Of forty-eight cases collected and analyzed, in three acute obstruction occurred.[3] In four cases hypertrophied turbinated bodies and polypi were found. In fourteen cases injuries by blows, falls, etc., were the primary cause of the affection.[4] In one-half the entire number of forty-eight cases there was nothing in either the history or the condition to suggest the origin of the disease, although there are strong reasons for believing that it had its origin in some intra-nasal affection which blocked up the infundibulum.

The course of the disease may be exceedingly rapid or very slow. In the first instance the empyema is due directly to accumulation of pus. In the more chronic cases the distention is first caused by the presence of mucus, which afterward becomes changed into muco-pus by bacterial infection. Necrosis following periostitis may be one of the results of the diseased condition of the mucous membrane, or it may precede it and act as a cause of the disease.

The orbital plate of the frontal bone first yields to the effects of the pressure, and, from its comparative thinness, may give way. In this way a swelling at the root of the nose and at the upper and inner margin of the orbit is formed, which may be mistaken for an inflammation and distention of the lachrymal sac. Where necrosis is either the cause or the result of the disease, the swelling may be found at some other portion of the sinus wall. The swelling is usually one-sided, whatever be the situation of the diseased area, for the reason that disease of both sinuses is extremely rare.

The symptoms are—frontal headache, the pain frequently following the course of distribution of the supra-orbital nerve. Chills, rise of temperature, and a general malaise are also experienced. To these are to be added the symptoms of a severe coryza, with inability to respire through the nose, and discharge of mucus or muco-pus. Lachrymation may be present. Perforation of the sinus may occur posteriorly, in which event circumscribed or diffused septic meningitis may occur. The severity of these symptoms will vary with the acute or subacute character of the case.

The chronic cases come on insidiously, with moderate frontal pain and a feeling of distention in that region, and occasional discharge from the nose. As the fluid slowly accumulates there is a tendency to protrusion of the globe of the eye, due to the pressure from above downward and outward. As absorption of the bone proceeds, a sense of fluctuation, at first obscure and afterward more pronounced, is felt. In both the acute and chronic forms, as the contents approach the surface, there occurs infection of the structures overlying the bone; œdema and swelling, with an erysipelatous blush, are observed. In fact these cases may readily be mistaken for true infectious erysipelas. The tumor may vary in size by reason of an occasional partial emptying of its contents through the nose.

Among the complications of empyema of the frontal sinuses may be mentioned disturbances of the visual organs, brain symptoms, and those referable to the naso-pharyngeal cavity. Diplopia and ptosis are sometimes present. Variations in visual capacity may result from variations in the degree of pressure upon the globe, according as the neighboring swelling increases or decreases in size; even total loss of vision has been reported. The empyema, by perforating posteriorly, may give rise to secondary abscess of the anterior lobe of the brain. Cerebral involvement may be preceded by anosmia and symptoms of optic neuritis. As a result of the blocking up of the air-passages, mouth-breathing and a very distressing dryness of the pharyngeal cavity are likely to be observed. The sense of smell is lost, and frequently the sense of taste as well.

The treatment of empyema of the frontal sinus consists in gaining access to the cavity by making an opening into the anterior wall of the sinus, thoroughly cleaning the same, and then providing for efficient drainage. An exploratory puncture, in case of doubt, may precede the formal operation. In exposing the bone, the incision in the soft parts should commence at the inner extremity of the shaven eyebrow, where no supraorbital notch can be felt (a foramen existing instead), and should extend outward not more than an inch from the median line. By this means the vessels and nerves will certainly escape injury (Dawbarn). The opening through the bone may be made by the dental engine and trephine, but a small chisel and wooden mallet will be found to be the most generally available instruments for the purpose. The drainage through the nose is the most important part of the treatment. Soelberg Wells claims to be able to accomplish this without external opening by passing an instrument upward from the nose into the sinus. Save in favorable cases this will be found to be very difficult. In opening into the nose from the floor of the sinus, after the latter has been opened, the operator's little finger should be passed into the nostril of the same side to act as a guide. Through and through drainage, by means of a perforated drainage-tube of rubber, should then be instituted. Mild astringent and antiseptic solutions, such as boro-salicylic or Thiersch's, a saturated solution of boracic acid or pyoktan in (2 to 1,000), should be employed.[5]

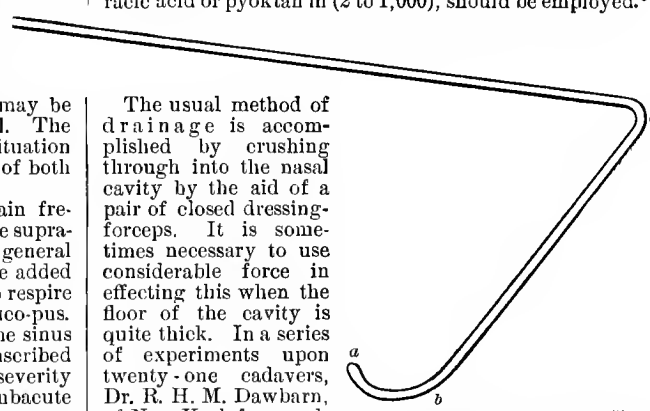

FIG. 162. — Dawbarn's Frontal Sinus Probe. The distance from *a* to *b* is about half an inch, and that from *b* to *c* should be the distance from the incision in the eyebrow to the nostril. The latter distance, therefore, will vary much, according to the length of the nose.

The usual method of drainage is accomplished by crushing through into the nasal cavity by the aid of a pair of closed dressing-forceps. It is sometimes necessary to use considerable force in effecting this when the floor of the cavity is quite thick. In a series of experiments upon twenty-one cadavers, Dr. R. H. M. Dawbarn, of New York,[6] succeeded, in all but one, in passing a peculiarly bent probe (Fig. 162) down the natural passage, through the middle meatus, and into the nose, and thence out of the nostril. A thread is then to be tied to the end of the probe as it projects from the nostril, and the probe is to be withdrawn. The operator now has a thread which passes from the nostril and nose through the middle

meatus and infundibulum into the frontal sinus. To this may be attached either a small drainage-tube or a strip of iodoform gauze, and by withdrawing the thread the drain is brought into position. The plan here suggested is worth a trial, for if the drainage can be efficiently applied by Dawbarn's method, it would be a barbarous procedure, in comparison, to crush through the outer plate of bone, as usually taught in the text-books.

In the series of forty-five cases collected by Richards, death occurred in six; one of these perished through albuminuria and another from meningitis. The remaining four died from secondary cerebral abscess.

George Ryerson Fowler.

GALLACETOPHENONE. This substance has been introduced as a substitute for pyrogallic acid in the treatment of psoriasis and similar skin diseases. A commercial name for it is "alizarine-yellow C." Chemically it is a tri-hydroxy-benzene, in which a fourth hydrogen atom has been replaced by an acetyl group. Its formula is $CH_3CO.C_6H_2(OH_3)$. It is prepared by treating pyrogallic acid with acetic acid in the presence of chloride of zinc. It is a pale yellow powder, almost insoluble in cold water, very soluble in hot water, alcohol, ether, and glycerine. The presence of acetate of sodium increases its solubility in cold water: one drachm may be retained in solution in three and a half ounces of water by the addition of one ounce of sodium acetate.

It is a powerful antiseptic; a one per cent. solution will prevent the putrefaction of chopped meat for twenty-one days.

The chief advantage which is claimed for it, as a substitute for pyrogallic acid, is its freedom from irritating and toxic properties. Experiments on animals prove it to be non-poisonous. It has been shown that dogs will bear a dose of one drachm daily for a long time without inconvenience. This is due to the fact that it oxidizes very slowly. Pyrogallic acid is too rapid and energetic in its action: it has at times caused very serious disturbances, and fatal results have followed its external use, these ill effects being due to its intense reducing power, particularly in alkaline solution. Another advantage of the new drug is that it does not soil the linen when used.

The use of gallacetophenone in skin disease was introduced by Dr. L. von Rekowski, of Professor Nencki's Institute, at Berne (*Therapeutische Monatshefte*, September, 1891). It was used in psoriasis with very satisfactory results, the beneficial effects of the treatment being noticed within twelve hours. In a short time the patches become paler and thinner, and desquamation lessens. After ten or twelve days the patches have almost disappeared, and in two or three weeks a perfect cure is effected.

Dr. Hermann Goldenberg, in the *New York Medical Journal*, February 6, 1892, reports his success with it in several severe cases of long duration. He considers it much superior to pyrogallic acid or chrysarobin, and perfectly harmless. It also proved of service in some cases of eczema. There is no irritation of the skin, nor staining of the skin, hair, or clothing. The drug is used in the strength of ten per cent., as an ointment, with vaseline, or in solution. *Beaumont Small.*

GALL-BLADDER AND DUCTS, SURGERY OF. The domain of surgery has been extended during the last decade so as to include the disorders arising from biliary obstructions, which were formerly relegated to the list of irremediable cases. While Bobbs did an operation upon the gall-bladder incidentally, in seeking to remedy a trouble which was not clearly understood, Sims resorted to a measure subsequently, with a distinct object in view, which led to investigations by others, in connection with the gall-bladder, of vast importance. The experiments upon inferior animals, which were made by me, looked to a different result in the disposition of the bile from that which was contemplated, in the external discharge of it through a fistulous opening, by Sims. Winiwarter, without my knowledge, had sought to convey the bile into the intestinal canal, and had thus succeeded in relieving the troubles growing out of obstruction of the common bile-duct. On this line my efforts were directed to clearing up some of the difficulties in the accomplishment of a communication from the gall-bladder into the duodenum or the adjacent small intestines.

A careful examination of several articles contributed to the second volume of the HANDBOOK, entitled "Cholecystectomy, Cholecystotomy, and Duodenocholecystostomy," should premise a consideration of the data now presented to the profession. It will be learned that the principles and processes of the various operative procedures were fully elaborated, and the reader will be prepared to comprehend what advances have been made in the surgery of the gall-bladder and ducts since that period. There has been some modification of the different operations originally undertaken, but no material improvement in the steps inculcated for cholecystectomy and cholecystotomy; while new departures are noted principally in the excision of gall-stones from the ducts, and in the attachment of the gall-bladder to different portions of the intestinal canal, with a fistulous communication between the former and the latter. The use of gauze tamponage in operations involving the integrity of the gall-ducts, either around drainage-tubes or without them, has been attended with such favorable results as to commend this procedure to surgeons. While a case reported by Lane, and facts occurring in the experience of other operators, lead to the conclusion that the presence of freshly secreted bile in the peritoneum is not attended with any serious consequences, it is certainly very desirable to prevent its entrance into the cavity of the abdomen. It is principally with a view to circumscribe the collection of bile from lesions of the ducts, either accidental or in operations, that gauze packing in the immediate vicinity of biliary exudation has been resorted to of late. When the layers of iodoform gauze are extended from the site of an incised or lacerated duct to the external abdominal opening, it is claimed that it serves to carry out the bile by capillary drainage, even when no drainage-tube is employed. It is further held that by pressure upon the surrounding parts the extravasation of the bile into the structures is obviated, so that in suturing the ducts or the gall-bladder, with or without anastomosis with the intestinal canal, it is a wise precaution to fill up the intervening space with strips of iodoform gauze.

The operation of cholecystectomy, which was introduced by Langenbuch, has been practised eight times by Terrier, with seven recoveries. Michaux performed this operation in two cases, and both resulted in cure. Dawson reports a successful cholecystectomy for impacted gall-stones, which were faceted and weighed respectively 79, 80, and 81 grains. Czerny gives two cures by cholecystectomy, and this process affords highly satisfactory results. Other successful operations have been done in this country and in Europe, and the fatal results have been comparatively small. The number of operations reaches in all nearly one hundred, with a mortality of less than twenty per cent. This operation is contra-indicated in cases of obliteration of the ductus communis choledochus. But when this is patent, and there is occlusion of the cystic duct, with greater or less disorganization of the gall-bladder, so as to preclude its restoration, it is indicated. Biliary fistulæ, from the accumulation of gall-stones, would also warrant cholecystectomy. In view of the favorable results reported, surgeons will not hesitate to avail themselves of this recourse in suitable cases, notwithstanding the opposition of those who have no experience in its performance.

The operations of cholecystotomy and cholecystostomy have been practised extensively during the period which has intervened since the publication of my articles in the second volume of the REFERENCE HANDBOOK. The

former designation is applied to those cases in which the obstructions have been removed through an incision in the walls of the gall-bladder and afterward the opening is closed by sutures, when the viscus is either dropped or secured to the edges of the external wound. This last procedure, urged by Sanger and Wölfler, is intended to allow of the escape of bile externally, if the stitches yield, instead of being discharged into the peritoneal cavity. The term cholecystostomy is used for those cases having the incision in the gall-bladder left open and attached to the opening in the parietes, so as to allow of the flow of bile externally. This procedure has been adopted upon the supposition that eventually the bile would find its way through the common duct, and that the external opening might close, either spontaneously, or through the instrumentality of a plastic operation. The results of this procedure have not been always satisfactory, and it is not so free from risk as has been claimed by some who urge its adoption in preference to other measures. It cannot afford more than temporary relief in cases of occlusion of the common bile-duct, and entails upon the sufferer the very condition of a biliary fistula, which has furnished the reason, in many instances, for seeking surgical assistance. In two cases of pronounced cholæmia from the closure of the common bile-duct, which have come under my observation, a resort to the operation of cholecystostomy failed to arrest a fatal termination. Although in each case there was a free discharge of bile through the opening made by attaching the edges of the incision in the gall-bladder to the sides of the cut in the abdominal wall, no benefit was derived from either operation, and both patients (females) died in less than a week after undergoing the operation. It is proper to state, in this connection, that no gall-stones were found in the gall-bladder or in the ducts of either of these patients, and that the obstruction of the common bile-duct resulted from adhesive inflammation of its coats, by which the canal was reduced to a hard, dense cord. The previous history of clay-colored stools and profound jaundice, with distention of the gall-bladder, showed cholæmia in both.

The intermediate process of incising the wall of the abdomen only, and attaching the wall of the gall-bladder unopened to its edges, with gauze placed in the wound until adhesions have occurred, when an opening is made into the gall-bladder, has nothing whatever to recommend it. The most instructive digital examination of the gall-bladder and ducts is precluded by this procedure, and it affords no facilities for the removal of obstructions which may exist in the cystic or common ducts. Notwithstanding the endorsement by Riedel of the performance of this operation at two sittings, Körte, who has performed it in two cases, prefers the operation as performed at one sitting, when it is possible.

When the ductus choledochus is found free, and the cystic duct can be rid of obstructions, the most satisfactory proceeding is the immediate closure of the incision in the gall-bladder and its return into the abdomen, without any attachment to the parietes. This course has now been adopted in a sufficient number of cases, with a good result, to satisfy the profession of its efficacy in restoring the normal relations of the gall-bladder.

Catheterization of the cystic and common bile-ducts has been undertaken in a limited number of cases with satisfactory results. It is held by Terrier and Daily that it is easier under pathological conditions, but the catheterization should be undertaken with a clear idea of the normal relations for a guide to the operation.

The process of disintegration of biliary concretions by the introduction of a needle into the mass and breaking up its structure, has been found advantageous in dislodging obstructions of the ducts. In connection with this, the use of padded forceps or pressure with the thumb and index-finger for crushing the gall-stones, has been attended with good results in some cases.

In cases where it is impracticable to unite the gall-bladder with the intestinal canal, an attempt has been made in a few instances to bring about a communication, by incision and suture, between the ductus communis and the duodenum or a coil of the small intestine. A successful case is reported by Sprengel. But the difficulties attending this operation offer little encouragement to its repetition. The most striking developments in this department of surgery look to the restoration of the bile to the intestinal canal.

None of these procedures is adapted to relieve impaction of the ducts by gall-stones, or the agglutination of their walls from plastic inflammation of the tissues. Other measures have been resorted to within the past few years, which constitute the most notable advances in the surgery of the gall-bladder and ducts. The excision of biliary calculi, which are so hard as to resist crushing in the ducts, has been practised successfully. After incising the coats of the cystic or common bile-ducts and removing the concretions by forceps or other means, the opening has been closed by suture, and a satisfactory result has been obtained in a large proportion of the cases reported. Not only has the incision healed kindly, but the duct has conveyed the bile to its proper destination.

Incision and suture of the walls of the common bile-duct, with the removal of gall-stones, have been resorted to in thirteen cases, with two fatal results. Three of these operations have been done by Courvoisier, and one by each of the following: Kummell, Heusner, Kuster, Rehn, Braun, Frank, Hocheneg, Thornton, Marcy, and Vander Veer. A stone has also been successfully excised from the cystic duct by Ross.

There is a class of cases in which nothing can avail to remove the occlusion of the ductus communis choledochus, and the recourse for the surgeon is to secure a communication from the common duct above the obstruction, or from the gall-bladder, with the duodenum or some adjacent portion of the intestinal canal. The best efforts of operators have been directed to this end of late, and what was foreshadowed in my contribution on duodeno-cholecystostomy seven years ago, has now been realized in a sufficient number of cases to guarantee the future success of this operation. In nothing undertaken during the last decade has the triumph of intelligent effort been so marked as in overcoming the difficulties connected with complete obstruction of the common bile-duct. Temporary obstacles may yield to various devices which have been adopted, but the impermeable agglutination of the coats of the common bile-duct can only be remedied by opening up a new route for the passage of the bile into the intestinal canal. It is begging the question to allege that any process can restore the canal when it is permanently occluded by agglutination of its walls.

In my opening address, as chairman of the Surgical Section at the meeting of the American Medical Association in Detroit, some data upon the surgery of the gall-bladder and ducts were presented which may be appropriately incorporated in this paper. It was demonstrated that all cases of the obstruction of the cystic and common ducts by gall-stones call for their dislodgement by one or another procedure, to afford an outlet for the bile; and that the attachment of the incision in the gall-bladder to the opening in the wall of the abdomen for a discharge of the bile externally, should be regarded as a mere temporary recourse. In the event of failure to effect an outlet for the bile through the common duct, then cholecystenterostomy is clearly indicated. As to the portion of the intestine which should be selected for the attachment of the gall-bladder or the ductus choledochus, we have a definite guide in the entrance of the bile naturally into the duodenum; and the nearer to this an anastomosis can be effected, the better result may be expected. The relations of the duodenum and jejunum to the gall-bladder, ordinarily, are such as to facilitate their union, and I have given the preference to the duodenum from physiological considerations as well as from surgical convenience, while objecting to the colon.

It is, of course, presumed that there is such an occlusion of the common bile-duct as to prove irremediable by other means, before proceeding with an operation to effect an outlet for the bile by uniting the gall-bladder with the intestinal canal. A misunderstanding of this condition has led to misapprehension of the end to be

attained by duodeno-cholecystostomy or cholecystenterostomy; and let me say, once for all, it is only warranted by occlusion of the common duct.

In this connection the following pointed remarks of Greig Smith upon entero-cholecystotomy, in the last edition of his work on abdominal surgery, place my investigations upon this subject in a proper light before the profession:

"By this operation is meant the establishment of a fistula between the gall-bladder and the intestine. The operation is indicated only in cases of incurable biliary fistula; that is, in cases where there is insuperable occlusion in the ductus communis choledochus. The original operation of Winiwarter successfully established a communication between the gall-bladder and the colon. In this situation the physiological effects of the biliary secretion were lost. Dr. Gaston, of Atlanta, Ga., in a series of instructive experiments on dogs, showed how communication might be established between the duodenum and the gall-bladder, thus preserving in the system whatever value the bile may have. Gaston speaks of his operation as duodeno-cholecystostomy. Some misconceptions and misdirected criticisms of Gaston's operation have appeared in various journals; to those he has given satisfactory answers."

In the comprehensive and elaborate record by Courvoisier of what has been accomplished for the relief of biliary obstruction, he states that my experiments on animals were undertaken in the hope thereby of clearing up the way for a practicable future operation on man. His remarks on this point are quoted: "Gaston sought to utilize the elastic ligature. In five dogs he carried it through the approximated walls of the gall-bladder and duodenum, in such a way that one-half of the tightly drawn loop lay in the former, the other half in the latter. The loop was to cut through both walls at the same time and thus form a fistula between both cavities. At the close of his operations Gaston placed a catgut suture around the place where the walls of the organs lay in apposition. In one animal the adhesions were completed by the eleventh day, and in this case there was a beautiful fistula, while the ligature had passed off through the intestine. In 1884 Gaston also made an experiment on a young dog with a silk ligature, and obtained a good result. Later on, he repeated these experiments with ligation of the common duct, without satisfactory results."

Courvoisier further states that Golzi reports five experiments on dogs. The common bile-duct was ligated. Then, with a catgut suture, the surfaces of the gall-bladder and the nearest loop of the small intestine were stitched around a loop of suture, passed through each wall so as to cut through. It is stated that the animals bore the operations without material derangement of the digestion.

It is also noted by Courvoisier that Page operated in the same manner as Golzi did on three dogs, omitting, however, the ligation of the common duct. One dog survived, one sank with peritonitis, and the third died after six weeks, showing a considerable shrinkage of the gall-bladder, but without any fistula. The result is not known in the dog which survived.

The various procedures adopted by Golzi, Page, and myself were undertaken with a view to guide others in the performance of operations upon human beings. All must allow that the fruit of our experiences has thrown much light upon the intestinal labyrinth in which we groped without a guide to direct us at that period.

The difficulties encountered by me in ligating the common bile-duct subsequently, were the greatest obstacles to the final success of this operation, and would not be encountered in case of pre-existing occlusion, which is the occasion of performing an operation on the human subject.

These and other experiments, undertaken upon twenty-one dogs, are fully illustrated by the cuts accompanying my contribution upon "Duodeno-cholecystostomy" in the second volume of the REFERENCE HANDBOOK.

It may be stated that my conception of the procedures indicated was not limited to the means employed in these experiments, and it was distinctly set forth that some other process might be found preferable, and it rests with surgeons to adopt that which proves best.

To Nussbaum is attributed the first suggestion of relieving the occlusion of the common bile-duct, by discharging the bile into the intestinal canal through artificial openings in the adherent walls of the gall-bladder and the intestine. But the credit of having first accomplished this result upon the human being is undoubtedly due to Von Winiwarter, and it affords me the greatest satisfaction to award him the honor of priority in the execution of cholecystenterostomy in 1881.

After a lapse of six years Monastyrski united the gall-bladder with the jejunum on the fourth of June, 1887. He incised the abdominal wall, punctured the gall-bladder, incised its walls and the jejunum, and sewed the edges with catgut. A fistulous communication was secured two metres below the duodenum, but death ensued from carcinoma of pancreas, as verified by autopsy.

The operation of Kappeler came next in the order of time, being done on the sixth of July, 1887, by uniting the gall-bladder with the ileum by Wölfler's suture. The patient progressed favorably for a time and returned to work, but eventually died on September 9, 1888, fifteen months after the operation. The autopsy showed that a biliary fistula was established about eight feet from the ileo-cæcal valve, and that its intestinal orifice was provided with a valve which allowed the contents of the gall-bladder to pass into the intestine, but prevented the passage of the intestinal contents into the gall-bladder. Doubtless, a similar provision exists in all such cases.

In the year following the operation of Kappeler, Fritzche accomplished a fistulous opening from the gall-bladder into the jejunum, three metres below the pylorus. At the post-mortem examination a carcinoma of the size of a walnut was found at the mouth of the common bile-duct.

Socin and Bardenheuer each attached the gall-bladder to a loop of the small intestine. The case of the latter died in the fourth week and no fistula was found. It is said to have been done with elastic ligature.

Robson operated, on March 2, 1889, upon a patient who had undergone a previous cholecystotomy, when the ducts were freed and the gall-bladder was sutured to the abdominal wall with firm adhesions. The common duct being subsequently occluded, an incision was made through the scar from the former operation, in the semilunar line, and it was found that the attachment of the gall-bladder could only be effected with the colon. Both were incised and united with chromicized catgut in two rows. The former external fistula was sewed up and a drainage-tube inserted in the wound. After one day bile came out of the drainage-tube, and also fecal matter came from the intestinal wound, mixed with bile, on March 5th. Afterward, up to the 18th, faces and bile continued to be discharged, and then bile alone, the wound granulating and ultimately completely closing on May 6th, when the motions were noticed to have regained their normal color. The patient reported herself in July as in perfect health.

Robson states that, "although Dr. Gaston proved the possibility of affixing the gall-bladder to the duodenum in dogs, and although this has been shown practicable in the human subject by Terrier's operation," he found that the difficulties are much greater than if a loop of the small intestine be selected.

On July 13, 1889, Terrier performed an operation for the relief of occlusion of the common duct. An incision was made in the median line, above the navel. The gall-bladder was punctured and the bile discharged. Upon incising its walls and exploring its cavity no stones were found, and the cystic duct was open. There was a gall-stone impacted in an oblong enlargement of the common duct which could not be removed. After attaching the gall-bladder to the duodenum by an oblong row of catgut sutures, and before tying the last stitches, the walls of both were incised and a rubber drainage-tube was introduced, so as to pass from the cavity of the gall-bladder into the duodenum. The fundus of the gall-bladder was sutured to the lower angle of the

external incision, which was then closed by a catgut suture. There was fever until August 1st, but the itching and jaundice gradually disappeared. The drainage-tube passed off with the evacuations nine days after the operation, and the stools gave evidence of the presence of bile. The external wound healed up by first intention. The patient was dismissed on August 10th, in ordinary health. The patient died in the spring of 1890, from influenza, and no gall-stone was found in the common duct.

Courvoisier, in like manner with Robson, performed the operation of natural cholecystotomy upon a patient without getting a satisfactory result. After the lapse of a year complications arose, which demanded cholecystenterostomy, and this was done March 28, 1890. An incision was made through the abdominal wall, below the ribs, along the border of the liver. The gall-bladder was detached from the abdominal wall, and after incising the sac a gall-stone was removed from the common duct and others were scraped from the hepatic ducts. An incision into the lower surface of the gall-bladder was united to the colon by an oval row of catgut sutures, and before putting in the last stitches the wall of the colon was incised. The fistulous parts of the gall-bladder were cut away and the edges stitched up. Two drainage-tubes were inserted and the external wound closed around them. There was no fever after April 2d. Bile was found on the dressings, but its source was not determined. There was bile in the stools on April 6th, and on the 8th the drainage-tubes were removed and the external wound was stitched up. On April 15th the patient was free from jaundice and got up feeling very well. The case was dismissed about the middle of May, and in July her condition was good.

A successful case of cholecystenterostomy has been reported, on February 25, 1892, as done by Helferich. The patient, a man, aged twenty-nine, had suffered periodically from pains in the stomach since 1885, and developed jaundice in April, 1891. During the following month he had attacks of biliary colic, recurring every fortnight, the jaundice being marked after each attack. It was thought that the common duct was obstructed by calculi, and an operation for their removal was undertaken in November. An incision was made midway between the lower border of the ribs and the border of the enlarged liver, extending vertically in the linea alba to the ensiform cartilage. After the liver had been retracted, the gall-bladder came into view; it contained no calculi, but an examination disclosed a number of calculi in the common bile-duct, which it was found impracticable to remove. An opening was therefore made in the gall-bladder and another in the first part of the jejunum, and a communication was established between these two structures by suturing the corresponding margins of the apertures. The fistula thus formed was of the calibre of a lead-pencil. The patient made a rapid recovery, with disappearance of the jaundice.

Körte reports a favorable result of the union of the gall-bladder with the wall of the duodenum, after the process of Terrier, thus affording two successful cases of duodeno-cholecystostomy.

He states that the patient, after having shown total acholia in the fæces for four weeks, was operated upon. He was, however, unable to lay bare the choledochus, and it remained uncertain as to whether the obstruction was caused by stones or cicatricial stenosis; the indications were, however, in favor of the latter diagnosis. Finding himself completely thwarted in his efforts to lay bare the gall-passages, he determined to establish an anastomosis between the gall-bladder and the duodenum. He sewed the gall-bladder to the bowel, opened both organs, and then stitched the edges of the cuts together. The act of applying a suture so deep in the abdominal cavity constituted not only a difficult, but most tedious, undertaking. For the sake of precaution he wound a strip of iodoform gauze around the suture and kept part of the abdominal wound open. The suture uniting the gall-bladder and intestine healed well and the bile began to flow into the intestine. No bile was ever discharged through the wound to mar the cure.

Richelet performed this operation in one case. The gall-bladder was secured to the duodenum. The results were not very satisfactory, biliary retention persisted, and a second laparotomy was performed, the gall-bladder was opened, and an effort was made to extract the calculus. This resulted in a hemorrhage so severe that death resulted in an hour. At the autopsy it was found that the forceps had seized a calculus, which was so firmly adherent that its displacement had caused tearing of the gall-bladder and had resulted in hemorrhage.

A case of temporary cure is reported by Czerny for occlusion of the choledochus by the operation of cholecystoduodenostomy. This makes four recorded operations by the process which I have designated as duodenocholecystostomy, with favorable results in three of the cases; and the miscarriage in the fourth case was due to an accidental lesion in the extraction of a gall-stone by forceps in the performance of a second laparotomy. It is evident in this case that Richelet had overlooked an essential condition for success in his first operation, by attaching the gall-bladder to the duodenum without taking the precaution to remove the calculus from the cystic duct.

Choleeystocolostomy was performed in one case by Czerny, in occlusion of the ductus choledochus by a calculus. The immediate result of the operation appeared satisfactory, but death occurred two weeks afterward from hemorrhage.

Another operation reported by Czerny presents features of interest, which warrant a record of some details of this case of cholecystenterostomy after temporary cholecystotomy.

A vertical incision was made through the right rectus muscle. The enlarged blackish-yellow liver presented itself in the opening, and on its side was the very tense gall-bladder of the size of a fist. Puncture of the latter yielded 300 c.c. of a clear, watery fluid. The sound could be entered a distance of 14 ctm. through this puncture without meeting with calculi, but its further progress was arrested by some obstruction. Neither concretions nor any tumors could be detected by palpation. An obstruction of the ductus choledochus was suspected, but no cause could be found for it, and a temporary biliary fistula, opening externally, was established in place of the cholecystenterostomy, in order to remove if necessary, later on, the obstruction in the duct, through the gall-bladder. The peritoneal covering of the gall-bladder was stitched to the parietal peritoneum. A part of the abdominal incision was closed, and the opening in the gall-bladder occluded by applying a Péan clamp forceps. Two days after the operation, when the dressing was changed for the first time, 500 c.c. of pure bile rushed forth as soon as the Péan forceps was removed. The unknown obstruction in the ductus cysticus was thus removed. Pure bile was now discharged regularly, but in spite of this, the existing icterus diminished but slowly, and never disappeared entirely; the urine contained, continually, more or less bile, and the fæces were entirely acholic. Therefore, the occlusion seemed not to have been perfectly removed, and cholecystoenterostomy was performed two months after the establishment of the fistula. The fistula was now temporarily closed by sutures, and the existing opening into the abdominal cavity was elongated above and below. The separation of the gall-bladder from the parietes could not be accomplished without injuring its walls, which had several rents. The injured part of the wall of this organ was extirpated, and the resulting circular opening was diminished by two rows of catgut sutures to the size of a bean. A loop of small intestine was then drawn out and united to the posterior wall of the gall-bladder by means of five sutures in the serosa. An incision 1½ ctm. long was then made in the small intestine, thirteen anterior and posterior sutures through the mucosa were inserted, and finally nine sutures through the serosa were applied. Drainage was effected by means of iodoform wick, and the abdominal wound was closed around it.

Temporary improvement followed. Soon afterward, however, the patient sank rapidly and death took place

from exhaustion, induced by cancer of the pancreas, gangrene of the lungs, and other complications. The fatal result occurred three months after the operation, and hence was not a direct consequence of the union of the gall-bladder and the intestine.

An interesting case, in which an anastomosis between the gall-bladder and colon was effected by a process differing materially from the previous operations has been reported by Chavasse.

A man, forty-eight years old, had undergone cholecystotomy for relief of jaundice dependent upon biliary obstruction by calculi, which was followed by the persistence of a biliary fistula. Other means failing, with the aid of Senn's bone-plates, a communication was established between the gall-bladder and the colon at its hepatic flexure. At first, bile and fecal matter were discharged through the abdominal wound, but ultimately this closed, the stools were passed naturally, and the general condition of the patient was much improved.

Further experience with this process may prove as satisfactory as its use in intestinal anastomosis. The increasing interest exhibited by surgeons in the serious consequences resulting from any obstruction to the discharge of bile is strikingly manifested by these aggressive measures, and a new era has dawned upon gall-bladder surgery.

A revolution has been brought about not only in the theoretic views of surgeons, but in the appliances resorted to in the surgery of the gall-bladder and ducts, which encourages the expectation of obtaining a satisfactory solution of the problem of relief for occlusion of the common bile-duct.

"A comparison," says Robson, "of the statistics of the different operations on the gall-bladder, as collected by Dr. Delaganière, would seem to show that although cholecystenterostomy is apparently the most complicated, it is the least dangerous operation."

The practicability of effecting an outlet from the gall-bladder into the duodenum or the intestinal canal, can no longer remain in doubt, and in the view of Courvoisier this operation stands more and more securely as the details from trustworthy sources become more widely disseminated.

Excluding from the reported cases those of a cancerous nature, all should be content with the results of the various procedures for uniting the gall-bladder and the common duct with the duodenum and intestinal canal.

The inferences to be drawn from a study of the results obtained in surgery of the gall-bladder and ducts are the following:

1. In all cases presenting a history of biliary obstruction with manifestation of enlarged gall-bladder, exploratory incision of the abdominal wall, and, conditionally, of the gall-bladder, is warranted.

2. When obstructions of the cystic and common ducts from gall-stones are found, they should be removed by needling, crushing, or incision of the duct and suturing the wound.

3. In case of the presence of a gall-stone in the cystic duct without impediment of the common duct, after removing the obstruction from the former, it would favor the restoration of normal conditions to close the incision in the walls of the gall-bladder without attachment to the parietes.

4. Should there be a degenerated or disorganized state of the coats of the gall-bladder, precluding the performance of its functions, the extirpation of the sac with ligation of the cystic duct will be proper.

5. Under circumstances of doubt as to the permeability of the cystic and common ducts, catheterization should be attempted with flexible bougies, guided by the fingers outside of the ducts.

6. In the event of an impermeable stricture or permanent obstruction of the common bile-duct, with a patulous cystic duct and good condition of the walls of the gall-bladder, the latter may be attached to the duodenum or adjacent portion of the small intestine, so as to effect a communication and thus admit of the passage of the bile.

7. Should the walls of the gall-bladder be likely to undergo disintegration and the walls of the common duct above the obstruction be in a favorable state, an incision in the duct may be united by suture with an incision in the duodenum or other part of the intestinal canal, to give exit to the bile.

8. While the results of a communication of the gall-bladder or common bile-duct with the duodenum or the upper part of the small intestine have proved more salutary than with the large intestine, there are cases in which the connection with the last named is alone practicable, and should be resorted to in preference to establishing an external fistulous opening.

9. Experiment has demonstrated the practicability of securing a union of the walls of the gall-bladder and duodenum with an opening by a single stitch of silk or elastic ligature, but the operations upon the human subject, attended with the best results, have been by incision and suture, with gauze tamponage.

10. The great importance of restoring the bile to the alimentary canal, in all cases of permanent occlusion of the common bile-duct, renders it desirable that an operation shall be undertaken at the earliest practicable period after obstruction to the flow of the bile into the duodenum is recognized as tending to cholæmia.

11. Cholecystotomy and cholecystostomy are not adequate to the relief of occlusion of the common bile-duct, and duodeno-cholecystostomy or cholecystenterostomy is indicated wherever it is evident that there is no outlet for the bile into the alimentary canal by the natural channel.

12. In the advanced stage of cholæmic intoxication from occlusion of the common bile-duct, there is such vital depression as to preclude any benefit from an operation, and it is only calculated to bring discredit upon the surgery of the gall-bladder and ducts to operate under such untoward conditions.

In 1889, Dastre communicated his experiments to the Physiological Congress at Basel, in which he united the gall-bladder with the intestinal canal with a view to study the effects on digestion. It was demonstrated that an animal can live without suffering from the loss of a portion of the bile from the upper part of the small intestines, and that a smaller quantity of bile than the natural secretion or excretion is sufficient for digestion. But the practical inference of most importance in connection with his experiments, is the feasibility of effecting a communication from the gall-bladder into the intestinal tract by incising and suturing their walls together in cases of total occlusion of the common bile-duct.

As in most cases requiring cholecystenterostomy it is requisite to make an incision of the wall of the gall-bladder for the removal of calculi from its cavity, or for proper exploration of the ducts, it is very desirable that some speedy process for suturing the edges of this incision to those of a like incision in the coat of the intestine shall be adopted. If mechanical devices can be dispensed with entirely in the junction of the gall-bladder and intestinal canal, and thus allow a free outlet for the bile, it is a consummation devoutly to be wished for in the performance of this important operation.

Lambotte reports a case, in the *Belgian Medical Press* of July 3, 1892, of external biliary fistula, resulting from cholecystostomy, for which he performed a unique operation. An incision was made in the abdominal wall in close proximity to the fistula, and a portion of the colon was drawn out through it. He then availed himself of the enterotrite of Dupuytren to effect a communication from the fistulous tract into the bowels, thereby conveying the bile off through the colon, instead of letting it flow out through the abdominal wall. The external fistulous opening was subsequently obliterated by a plastic operation.

The instrument presented by Grant at the late meeting of the Southern Surgical and Gynecological Association, at Louisville, Ky., for effecting intestinal anastomosis, meets the indications more satisfactorily than that of Dupuytren, for uniting the gall-bladder with the intestine. Although the author had not even suggested this application of his instrument, the writer submits

that a modification of the blades of this clamp, of such a nature that they can be carried through a small incision into the cavity of the gall-bladder and into the duodenum, or other portion of the intestine, would admit of the use of this instrument in effecting anastomosis of these viscera, and also in lateral intestinal anastomosis without resection.

A paper read before the Mississippi Valley Medical Association, October 15th, by Dr. J. B. Murphy, of Chicago, Ill., and published in the New York *Medical Record* of December 10, 1892, presents the details of a process styled "button anastomosis." It is the application of this procedure in cholecysto-intestinal operations which is of special interest for our investigation.

While this principle of anastomosis is not entirely new, having been adopted by another for uniting the viscera with an opening from one to the other, and by the writer in a case of gastrostomy reported at the Nashville meeting of the American Medical Association in 1890, yet the improvements in the mode of construction entitle Dr. Murphy to the claim of originality in the practical adaptation of the anastomosis button to this class of operations. I have the permission of the author to use his cuts for illustration.

He gives the following description of this device:

The buttons are made in three sizes. A button consists of two small circular bowls (Fig. 163); size No. 2 measures as follows: diameter, 23 mm.; depth, 8 mm. There is "sweated" into a circular opening, 12 mm. in diameter, at the bottom of one bowl, a cylinder 15 mm. in length, with female screw thread on its entire inner surface. The cylinder extends perpendicularly from bottom of bowl. There is an opening in the male bowl in which is "sweated" a similar and smaller cylinder of a size to easily slip into the female cylinder. There are two brass springs soldered on either side of the inner surface of the lower end of the male cylinder, which extend almost to the top, where small points of them protrude through openings in the cylinder. These points are designed to catch the screw-thread when the male cylinder is pressed into the female cylinder, and thus hold the bowls together at any point desired. To separate them again, they are simply unscrewed.

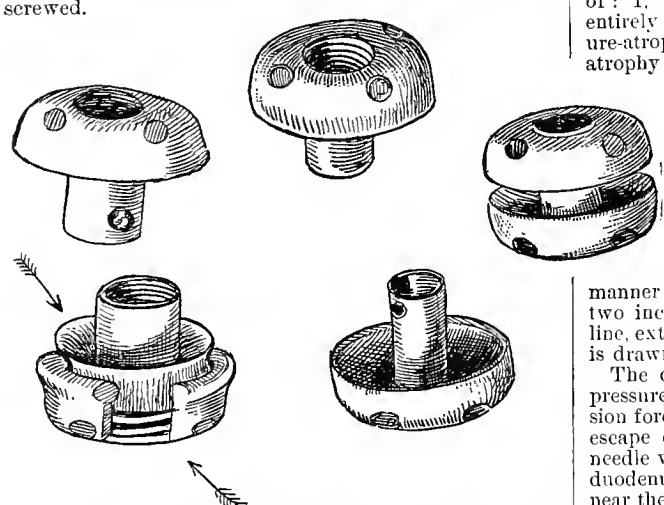

Fig. 163. Appearance of Button, with and without Spring-cup Attachment. (After Murphy.)

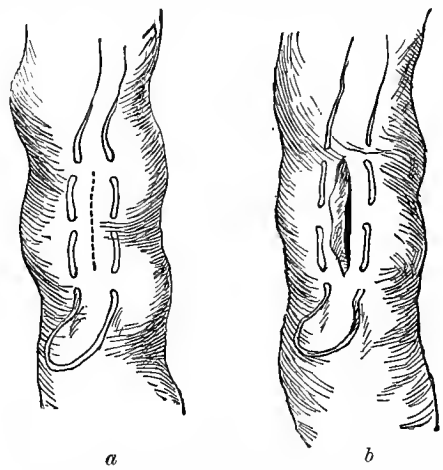
A small brass ring, with a thin though not cutting edge, to which is attached a wire spring, is placed in the male bowl and retained in position, projecting one-eighth of an inch above the edge of the bowl. This is held up by the wire spring, and is there for the purpose of keeping up continuous pressure until the entire tissue between the edges of the bowls is cut off. This spring attachment is absolutely necessary only when the stomach is operated on. There are four openings, 5 mm. in diameter, in the side of each bowl, for the purpose of drainage. By this, it will be seen, we have two hemispherical bodies held together by invaginating cylinders (Fig. 163). These hemispheres of the button are inserted in slits or ends of the viscera to be operated on. A running thread is placed around the slit in the viscus, so



a *b*

Fig. 164.—Showing Running Thread before (*a*) and after (*b*) Incision in Bowel. (After Murphy.)

that when it is tied it will draw the cut edges within the clasp of the bowl. A similar running thread is applied to the slit in the viscus into which the other half of the button is inserted, and the bowls are then pressed together. The pressure-atrophy at the edge of the bowl is produced by the brass ring supported by the wire spring. The opening left after the button has liberated itself is the size of the button.

Dr. Murphy claims that this differs from all other devices in the following particulars or combinations thereof: 1. It retains its position automatically; 2, it is entirely independent of sutures; 3, it produces a pressure-atrophy and adhesion of the surfaces at the line of atrophy; 4, it insures a perfect apposition of surfaces, without the danger of displacement; 5, it is applicable to the lateral, as well as to the end-to-end, approximation: 6, it produces a linear cicatrix, and thus insures a minimum of contraction; and 7, it has the merit of extreme simplicity of technique, which makes it a specially safe instrument in the hands of the every-day practitioner, as well as the more dexterous specialist. Dr. Murphy then describes the mode of application. The button is inserted in the following manner: An incision is made from the edge of the rib, two inches to the right of, and parallel to, the median line, extending downward three inches. The gall-bladder is drawn into the wound, and also the duodenum.

The duodenum is cleared of its contents by gentle pressure with the finger. His short intestinal compression forceps is placed upon the duodenum to prevent the escape of gas and fluids after the incision is made. A needle with fifteen inches of silk thread is inserted in the duodenum, directly opposite its mesentery and at a point near the head of the pancreas. A stitch is taken through the entire wall of bowel, one-third the length of the incision to be made. The needle is again inserted one-third the length of the incision from its outlet, in a line with the first, and brought out again, embracing the same amount of tissue as the first (Fig. 164). A loop three inches long is held here, and the needle is inserted in a similar manner, making two stitches parallel to the first in the reverse direction, and one-eighth of an inch from it, coming out at a point near the original insertion of the needle (Fig. 164). This forms a running thread which, when tightened, draws the incised edge of the

bowel within the cup of the button. In the gall-bladder a similar running thread is inserted. An incision is now made in the intestine, two-thirds the length of the diameter of the button used. The button is slipped in, in the manner hereafter to be shown, the running string tied, and the button held with the forceps.

The contents of the gall-bladder are withdrawn with an aspirator. An incision is then made in the gall-bladder of the same length, and between the rows of sutures, the button is inserted in a similar manner, and the running string tied. The serous surfaces to be approximated are scraped with the edge of a scalpel. The forceps is then removed and the two halves of the button are held between the fingers and pressed together (Fig. 165). A sufficient degree of pressure must be used to bring the serous surfaces of the gall-bladder and intestine firmly in contact and maintain pressure upon them. The elastic pressure of the spring-cup of the button produces a pressure-atrophy of the tissue embraced within the cup, and leaves an opening as large as the button, the latter dropping into the bowel and being passed through the intestines.

The time occupied in the case of the first woman on whom he operated was eleven minutes, from the entering of the peritoneal cavity until the closing of the same. On dogs he was from eleven to eighteen minutes in performing the operation. He states that the operation is more difficult to perform on the dog than on man, as it is more difficult to bring the gall-bladder into the wound.

Dr. Murphy draws attention to the number of cases of chronic jaundice from obstruction to the common gall-duct, requiring some operation for relief, and to the defects of the operations now in vogue, namely, the unpleasant and sometimes dangerous sequence of cholecystostomy —an external biliary fistula, which may of itself be a menace to life. He also adverts to the difficulties and dangers of cholecystectomy as a radical operation.

He says that the effect of a permanent fistula of the gall-bladder and the constant escape of bile secreted, as frequently follows cholecystostomy, is different, depending, first, on the quantity of bile that escapes from the opening, and second, upon what proportion is admitted into the intestinal tract. This accounts for the great differences of opinion as to the gravity of biliary fistula ; and if we let the entire quantity of bile escape through a fistula, the patient soon succumbs. Therefore, a safe way of allowing the bile to re-enter the intestine should be welcomed by the surgeon and the patient.

Dr. Murphy gives the result of five experiments upon dogs by uniting the gall-bladder and the duodenum with his anastomosis button, in three of which the animals were killed after the lapse of a month or more. It was found that the button had escaped, leaving an opening from the gall-bladder into the duodenum, with perfect union between their walls, and a valve was formed on the intestinal side of the opening by two folds of the mucous membrane closing over it, permitting the bile to flow out, but preventing the entrance of anything from the intestine. The writer would recall to the reader that this valvular provision was observed in the case operated upon by Kappeler, and reported in his description of the autopsy, the patient having died fourteen months after the cholecystenterostomy.

In one of the dogs, which was subjected to the same operation with the others, the additional experiment of tying the common duct was made and the result examined on the fourth day. A perfect adhesion of gall-bladder to bowel was found and the button was still in position. Hair and food were in the gall-bladder.

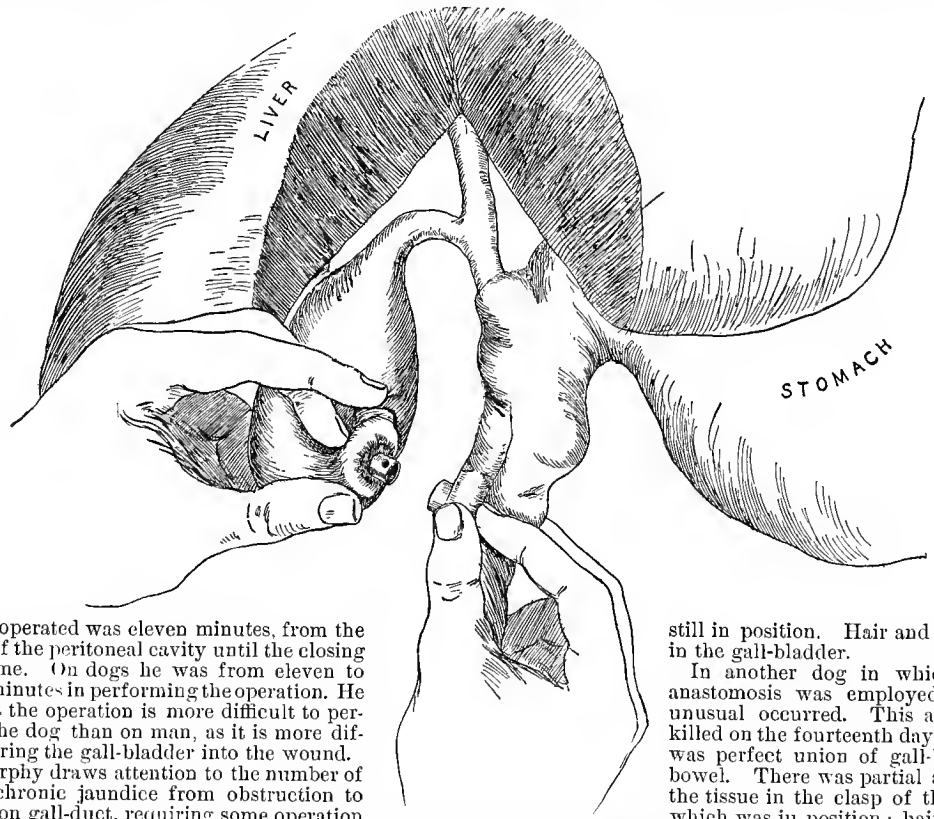


Fig. 165.—Button as Held when its Two Halves are Pressed together in the Performance of Cholecystenterostomy.

In another dog in which button anastomosis was employed, nothing unusual occurred. This animal was killed on the fourteenth day, and there was perfect union of gall-bladder to bowel. There was partial atrophy of the tissue in the clasp of the button, which was in position ; hair and food were in the gall-bladder, and the latter was of about the normal size.

An experiment was made upon one dog, with this modification : the stomach was used in place of the intestine for the anastomosis with the gall-bladder. A little difficulty was experienced in approximating the ends of the button, on account of the thickness of the wall of the stomach. The dog was sick on the following day ; would not eat or play. But on the third day all symptoms had disappeared. The dog was killed fifty-five days after the operation, and the gall-bladder was found to be firmly united to the stomach ; the little finger could be passed into the stomach from the gall-bladder, and there was neither hair nor food in the latter, which was somewhat contracted. The dog did not seem to suffer

any inconvenience from the bile passing into the stomach.

Three operations with the anastomosis button for effecting communication from the gall-bladder into the duodenum in the living human subject, have proved successful in the hands of Dr. Murphy. They were performed on June 11, October 19, and November 23, 1892, upon females aged thirty-five, thirty-eight, and thirty-six years. As the description of the second case embodies most of the points of interest in the operation, it will be given in the words of the author.

"October 19th, I made an incision, three inches long, from the edge of the tenth rib directly downward toward the border of the ilium. The tumor was exposed and found to be a very much enlarged gall-bladder, with large calculi within. The viscus was very œdematous, red, and thickened. It was decided to make a cholecystenterostomy with my anastomosis button (No. 2). The gall-bladder was aspirated and the running thread inserted. The running thread was then inserted into the duodenum and the intestine incised, and the male half of the button inserted; the female half was then inserted in the gall-bladder through a slit made between the running thread, and the button closed. There was no difficulty in inserting the button. The gall-stones were allowed to remain, as I do not consider it necessary to remove them unless they are larger than the button. They will pass out after the button escapes.

"October 20th.—Temperature, 101° F.; pulse, 96. Vomited considerably during the night and complained of headache, which seemed to be effects of the anæsthetic. There was no pain or abdominal tenderness.

"October 21st.—At 5 P.M. yesterday the vomiting ceased, and the patient is feeling very well this morning.

"October 27th.—The patient has had no unpleasant symptoms since October 20th. This morning, in the stool, were found two large gall-stones. The larger one weighed 117 grains (7.8 gm.); its longest diameter 1 inch, its shortest ½ inch. The second stone, 102 grains (6.8 gm.); shortest diameter ⅝ inch and its longest ⅞ inch. It will be noticed that the shortest diameter of the larger stone measures exactly the same as the diameter of button used.

"The patient is feeling very well and sitting up in bed. Complete primary union. Button passed eighteen days after operation."

Nothing is said by Dr. Murphy in regard to the further progress of this case, though his report of a patient subsequently operated on is brought down to November 28, 1892.

There seems to be some discrepancy in the dates of this paper, which was presented to the Association October 15th, containing reports of operations done on October 19 and November 23, 1892; but this may, perhaps, be explained upon the supposition that they were inserted afterward when the paper was published in the *Record*.

If the results of the experiments on dogs and the operations upon human subjects, reported by Dr. Murphy, are to be accepted by the profession as facts without criticism, we certainly have the most convincing proof of the superiority of the anastomosis button in this class of operations. There is an old adage that exceptions prove the rule, but there seems to be no discount to the uniform success of this new process of anastomosis for all the different tissues to which its author has applied it. He states that he performed the operation of gastro-enterostomy three times with the button on the human subject, and that Dr. Wiener did it once. "In all of the cases," he says, "we got a primary adhesion," and he adds that he will give a detailed report of these cases in a subsequent clinical paper on the subject.

Nothing is communicated as to the final outcome of the patients operated on excepting the first, but we are left to infer that all went well with them, as in a great variety of other successful operations with the anastomosis button referred to in this paper.

The writer has received specimens of three different sizes of these buttons from the manufacturer, and is convinced that a smaller button than either would be better suited to effect an opening from the gall-bladder into the duodenum. It is not desirable to have so large an outlet from the gall-bladder for the biliary discharges.

The two larger sizes of the button are of such bulk and weight that their passage through the small intestine may cause trouble, and more especially at the ileo-cæcal connection. It is a known fact that gall-stones, not exceeding greatly the diameter of the largest button, have been arrested in the small intestine, necessitating an operation for removal on account of the obstruction in the canal; and after examination of these buttons there seems to be cause for objecting to the employment of the larger sizes in attaching the gall-bladder to the duodenum. It will be observed that size No. 2 was used in the case recorded in this paper, and that the "button passed eighteen days after the operation." But nothing is reported as to the passage of the button in the other two cases. He states, however, that the patient operated upon on June 11, 1892, was examined by Dr. H. R. Wittmer on October 28th, and that she was in excellent health.

The weight of the buttons might be lessened materially by using aluminium in their construction, thus setting aside an objectionable feature, as the largest size at present weighs 340 grains.

Further experience in the use of the anastomosis button is desirable, before it is finally adopted in the surgery of the gall-bladder. *J. McFadden Gaston.*

GANGRENE. The subject of gangrene in its various forms was fully considered by the writer, in a previous article in the HANDBOOK, to which the reader is referred for a more extended discussion of the subject. It remains, however, to consider it from the stand-point of recent surgical pathology, more especially surgical bacteriology.

That form of gangrene which is due to lack of nutrition of the part, such as that caused by arteritis obliterans and by thrombosis, remains unaffected by recent experimental discoveries. We may therefore divide gangrene into two general classes—the first class being from lack of nutrition, and the second class being a gangrene of microbic origin. The first class, as has been known for a long period, includes alterations of the arteries and veins, and of the nerves of the arteries; these alterations consisting of atheroma, thrombosis, emboli, changes in the blood, and alterations in the structure of the nerves.

Reclus has given the term "direct gangrene" to the first class, including those produced by violent traumatism, by extreme cold, burns, and caustics; "indirect gangrene" to that series in which the lack of nutrition is due to arterial, venous, capillary, or cardiac derangements, and to the different alterations of the blood. The latter term is also applicable as well to the trophic or nervous gangrenes. Clinically, Reclus divides the gangrenes into four types: gangrene by cadaverization, white gangrene, dry gangrene, and moist gangrene.

Gangrene by cadaverization is an exceptional form, in which the skin is cold, dull, rigid, and discolored as after death, the epidermis is easily detached, and on puncturing the integument with a needle or by light strokes of the bistoury, small drops of blood appear. Sometimes the entire member is cold, but without being fatally lost, as in the case stated by Lemont, where after discoloration, coldness, and cornification, in about ten days there appeared, little by little, heat and sensation, and soon all traces of gangrene had disappeared. Ordinarily, however, says Reclus, the gangrene of cadaverization is succeeded by dry gangrene.

White gangrene, as described by Ousnay, appears in the same form and has been confounded with the gangrene of cadaverization. It appears as a hemorrhagic spot on the skin, a sort of limited ecchymosis, which may have its seat anywhere on the body; it is always superficial.

Dry gangrene, or mummification, is invariably produced by blocking of the blood-vessels or by trophic changes.

Moist gangrene applies to the septic variety, and is extremely rapid in its progress. Moist gangrene is distinctively septic, as has been proved by its reproduction by

inoculation, to such a degree that some pathologists have detached gangrenous septicæmia from the traumatic gangrenes.

As a means of determining the exact location of the thrombosis or obstruction, in the case of arteritis obliterans, Dr. W. S. Lyon, of Edinburgh, gives the following method of procedure: Gently raise the limb, keep it raised for two or three minutes to empty it in some degree of its blood, then apply the tourniquet or piece of elastic webbing on the proximal side of the injury or supposed site of the obstruction, and keep it applied for about a minute; then lower the limb and remove the tourniquet. If sufficient circulation remains in the part below the injury it will blush a rosy red and show in an unmistakable manner the condition of the blood-vessels. It must be evident that, as in the case of surface constriction when applied to a given surface, if the arteries are sound underneath, it will speedily cause tension below the ligature by reason of the accumulation of blood, and so, by readjusting the ligature from time to time, it is possible to approximately arrive at the site of obstruction.

Moist gangrene, or emphysematous gangrene, produced by the development of gases in the decomposed part, or putrefactive changes, is now supposed to be due to a bacillus morphologically like that of the malignant œdema, as described by Koch and Gaffney. It is known by the experiments of Rosenbach and others that in these cases of emphysematous gangrene there are present one or more varieties of the proteus micrococcus, with other forms of bacteria, and that the ptomaïnes of these bacteria themselves in some cases may cause tissue death; and that certain bacteria have the power of generating gases, this being true, in particular, of a variety which is called by the French "vibrion septique," which is anaërobic, and which resembles the bacillus anthracis. In this connection it is to be remembered that the treatment of moist gangrene has undergone a radical change; deep and thorough incisions, the injection of anti-bacillary agents, copious and repeated irrigation, are measures which are now practised, and amputation is reserved for cases in which the bones are so enfeebled as to be no longer capable of supporting the member.

It is evident from the mutiplicity of experiments and observations that no one microbe can be the sole cause of gangrene. Godlin[1] reported a case of gangrene resulting in emphysema, which started from an inflamed corn, rapidly extended, and in a week required thigh amputation. The man continued to show sapræmic symptoms after the amputation, and culture experiments with the pus showed the presence of streptococcus pyogenes and staphylococcus pyogenes albus. Lemont and Koch have described another bacillus which they found in a case of emphysematous gangrene, and which resembled the bacillus of glanders. Staphylococcus pyogenes aureus and staphylococcus cereus albus were found in metastatic gangrene of the skin, by Ciarrochi. He also isolated a short bacillus which, when injected under the skin of animals, produced gangrenous pus.

In conclusion it must be stated that the traumatic gangrene, where the parts are pulpified or bruised, and blood is extravasated into the tissues, affords favorable conditions for the growth and propagation of putrefactive bacteria. Senn has well summarized the etiology of septic gangrene as follows:

First Condition, the microbes are so numerous in the capillary vessels that their presence interferes mechanically with the blood-supply, and death of the part ensues in consequence of greatly diminished or suspended nutrition. *Second*, the microbes in the tissues produce ptomaïnes which destroy the tissue by their direct destructive chemical action on the protoplasm of the cells. *Third*, the specific inflammation caused by the microbic infection is so intense that the inflammatory product in the perivascular tissues accumulates so rapidly and in such abundance that nutrition is suspended by impairment or suspension of the arterial blood-supply, or mechanical interference of return of blood from the part, or both of these conditions combined.

Coagulative necrosis, a condition confounded by some with gangrene, was given its name by Cohnheim, and is a condition which takes place in the coagulation of the blood, whereby the colorless corpuscles die and undergo a fermentative change. This is the same as the "fibrine ferment" of the last decade. *John B. Hamilton.*

[1] British Medical Journal, July 27, 1887.

GAS ANALYSIS. I. General Properties of Gases.—(*a*) A gas is characterized by the property of filling uniformly any given space. If the pressure upon a gas be increased, its volume will diminish, and, providing the temperature remain constant, the volume of a gas will be inversely proportional to the pressure. Denoting the volumes by V and v, and the corresponding pressures by P and p, then,

$$V : v = p : P; \text{ or,}$$
$$(1)\quad VP = vp.$$

In other words, at a constant temperature the product of the volume and the pressure is always the same. This law of Boyle holds true only for relatively slight variations of pressure and volume. If it were correct for gases subjected to very great pressure, then the gas which would be first liquefied by the pressure would finally attain a density greater than solid substances, a phenomenon manifestly impossible, because liquid bodies are but slightly compressible. The variations from the law within the limits met with in ordinary analytical operations are, however, so slight, that for the present purposes it may be regarded as correct.

All gases expand in the same proportion when subjected to the same rise in temperature. If one volume of a gas be heated from 0° C. to 100° C., its volume then will be 1.367. The increase in volume for each degree would accordingly be .00367. If v is the volume at any temperature t, and V the volume at 0°, the above may be expressed.

$$(2)\quad v = V(1 + .00367\ t).$$

If a gas which has been thoroughly dried be collected over mercury in a tube closed at the top, and if then a small amount of water, sufficient to saturate the gas with water vapor, be introduced into the tube, it will be seen that the volume is thereby increased. In analytical operations it is quite difficult to dry each portion of gas before measuring, and in calculating the absolute volume of the gas, allowance is made for the increase in volume caused by the water vapor present. The pressure exerted by the water vapor has been determined experimentally for all temperatures, and the volume which a gas saturated with aqueous vapor would occupy if dry can be determined by ascertaining the volume which would correspond to the prevailing pressure, P, less the pressure exerted by the water vapor at the temperature observed. To illustrate, a gas volume saturated with water vapor, and measuring 63.2 cubic centimetres under a barometric pressure of 744.6 millimetres, and temperature of 18.4° C., would, in the dry state, and at the same pressure and temperature, equal $63.2\ \frac{744.6-15.72}{744.6}$ = 61.8 c.c., 15.72 being the tension of water vapor at 18.4° C.

It is evident that for scientific purposes, observed gas volumes should be reduced to the volumes which would be occupied under certain standard conditions. By common consent the pressure of a column of mercury 760 mm. high is termed the normal or standard pressure, and 0° C. the normal temperature. All observed gas volumes, then, are reduced to the volumes which the gases would occupy in a dry state at 760 mm. pressure and 0° C. The necessary data for the calculation have been given above.

In equation (1), if P be taken as the normal pressure of 760 mm., the equation becomes $V = \frac{vP}{760}$. Equation (2) would give for V, $V = \frac{v}{1 + .00367\ t}$. Combining

these two, and subtracting from the observed barometric pressure, P, the tension of the water vapor, m, at the observed temperature, t, we have

$$V = v \frac{P - m}{760\,(1 + .00367\,t)}.$$

To illustrate, 82.3 c.c. of a gas, measured in a moist condition under a barometric pressure of 748.2 mm., and a temperature of 18.6° C., would, under normal conditions, equal

$$82.3 \frac{748.2 - 15.91}{760\,(1 + .00367 \times 18.6)} = 74.1 \text{ c.c.}$$

(*b*) *Partial Pressure.*—Gases mix in all proportions. The pressure of the mixture is the sum of the pressures of the various gases in the mixture. The pressure exerted by each of the gases is the same as the gas would exert if present alone in unchanged amount in the same space. This pressure exerted by each gas of a mixture is known as its *partial pressure*. One hundred volumes of the atmosphere contain 20.9 volumes of oxygen and 79.1 volumes of nitrogen. If air were confined in a vessel under a pressure of 760 mm. and the oxygen were then removed, the remaining nitrogen would then fill the whole space and would exert a pressure of $760 \times 0.791 = 601.16$ mm. Had the nitrogen been removed, the oxygen would have exerted a pressure of $760 \times 0.209 = 158.84$ mm. These, then, are the partial pressures of the two chief constituents of the atmosphere.

The well-known researches of Paul Bert have shown that this partial pressure of atmospheric oxygen plays an important rôle in the process of breathing. We have seen above that the oxygen of the atmosphere exerts a pressure of about one-fifth of the total pressure of the air. Bert has shown that animals and men can live in pure oxygen if the pressure of the gas be reduced to one-fifth of an atmosphere, or, in other words, to the pressure which it exerts in the atmosphere. If, on the other hand, animals be confined in air whose pressure has been reduced to one-fifth of an atmosphere, death soon results, because here the partial pressure of the oxygen is only one-twenty-fifth of an atmosphere.

(*c*) *Diffusion of Gases.*—Molecules of gases move constantly in all directions, and if a layer of a light gas be carefully introduced over a layer of a heavier one, it will be found that, after some time, the lighter gas above has passed downward and mixed with the heavy gas below, and *vice versâ*. This property, known as diffusion, is possessed by all gases. Whenever different gases are in contact, the molecules of adjacent layers tend to intermingle and form homogeneous mixtures.

(*d*) *Solution of Gases in Liquids.*—All gases are more or less soluble in liquids, the amount dissolved depending upon the nature of the gas and solvent, and also upon the temperature and pressure. Gases which can be easily liquefied are more soluble than those which are liquefied only with difficulty, and, on the other hand, warming diminishes the solubility of the gas, perhaps because the rise of temperature removes the gas further from the liquefiable state. Henry, in 1830, found that at constant temperature the amount of gas dissolved is proportional to the pressure. That is, if a liquid absorbs a certain amount of gas at a pressure of one atmosphere, it will absorb twice as much of the gas under a pressure of two atmospheres, and at half an atmosphere half as much. This law of Henry is not absolutely correct, but it approaches the truth very closely for those gases which are but slightly soluble.

The amount of a gas taken up by an absorbent, as water, is determined by experiment with an "absorptiometer," such as that used by Bunsen,[2] or by L. W. Winkler,[9] and from the data thus obtained a table of the solubility of the gas at different temperatures can be made out. Bunsen denotes the solubility by the term "absorption-coefficient," by which he means the volume of gas reduced to 0° and 760 mm. pressure, which is absorbed by 1 c.c. of liquid at the same pressure.

It is important to remember in this connection that the solubility of a gas in a mixture of gases is not influenced by the presence of the other gases, and is not proportional to the total pressure of the mixture, but only to the pressure exerted by the gas in question, *i.e.*, its partial pressure. Thus water exposed to the air does not dissolve equal amounts of oxygen and nitrogen, nor amounts proportional to the solubility of the two gases, but rather the volumes of the two gases which the water will absorb depend upon both the solubility and the partial pressure of the two gases. To illustrate, the pressure exerted by nitrogen when the total atmospheric pressure is 760 mm. is about seventy-nine per cent. of 760, or 600.4 mm. At 760 mm. pressure and 20° C., 1 c.c. of water absorbs 0.014 c.c. of nitrogen; hence at 600.4 mm. pressure it would absorb $0.014 \times \frac{600.4}{760} = 0.0109$ c.c. Under the same conditions 1 c.c. of water dissolves $0.028 \frac{159.6}{760} = 0.0058$ c.c. of oxygen. Hence, when air is dissolved by water under the above conditions 65.2 per cent. of the dissolved gas would be nitrogen and 34.8 per cent. would be oxygen, or, in other words, the oxygen would amount to more than one-third of the total volume of dissolved gas, although in the air it amounts to one-fifth.

The law of partial pressure thus explains why the various components of a mixture of gases are taken up by a solvent in amounts depending upon the pressure of each gas and independent of the other gases present.

When the molecules of a gas come in contact with the surface of a solvent such as water, they are held fast or are absorbed, and this absorption continues until the water has taken up a certain number of the molecules. Some of the gas-molecules will meanwhile escape from the water and pass back into the gas, and when the number of molecules which enter the water in a given time is equalled by the number which escape, the water is said to be saturated with the gas. If the pressure of the gas be increased the number of molecules absorbed by the water will also be increased, and with diminished pressure the opposite will be true.

In the absorption of the gases in a mixture the amount of each gas absorbed will, as we have seen, depend upon the partial pressure of that gas, and the escape of the same gas from the water will be influenced by its own partial pressure in the mixture, but not by the pressure exerted by any other constituent. In other words, the atmosphere of another gas prevents the escape of a dissolved gas no more than would a vacuum. There are no molecules of the dissolved gas present to enter the water, and the gas, by reason of its elasticity, passes out. That many gases can be driven out of water by boiling, even although the gases are somewhat soluble in boiling water, may be explained by the fact that the surface of the water becomes covered with a layer of aqueous vapor, the partial pressure of the gas upon the surface of the water is thus made very slight, and, as a consequence, the dissolved gas escapes.

II. The Analysis of Gases.—(*a*) *The Collecting and Keeping of Gas Samples.*—In gas analysis, as in all other analytical work, the proper taking of the sample is one of the most important operations. Notwithstanding the rapid movement of gas molecules, currents of gases are often of varying composition, especially when chemical processes are simultaneously going on. On this account the place at which the samples of gas are taken is of the greatest significance. In pipes or other channels the point of smallest cross-section is the most suitable. In the examination of furnace gases it is best to take the sample at the point where the visible flame ends, because farther away, on account of the porosity of the wall, considerable quantities of air are always mixed with the gases from the fire. To take the sample an iron tube is introduced into the furnace at a suitable point. A small lead pipe, such as is used for pneumatic bells, is attached to the outer end of the iron tube by means of a piece of rubber tubing. At temperatures under 300° the lead pipe itself may be inserted into the furnace. The great

advantage possessed by such lead pipe is that it is very small internally and can be manipulated as easily as rubber tubing. For very high temperatures either porcelain tubes or cooled iron tubes may be used. With acid gases glass tubes should be employed if possible.

Long rubber tubes must be avoided, but short pieces may safely be used for connections. Rubber receivers also are to be rejected. Vulcanized rubber acts toward gases as does a liquid, absorbing the gases, and later, according to the prevailing pressure, giving them up again. For example, a piece of rubber tubing, 3 ctm. long and from 4 to 5 mm. external diameter, absorbed 0.2 c.c. of carbon dioxide and 0.9 c.c. of nitrous oxide, and on lying in the air it gradually gave up these gases.

If the place where the gases are to be collected is directly accessible, as, for example, in the examination of mine-gases, the small "medicine bottles" * proposed by Bunsen may be used, the neck of the bottle being drawn out in the flame of the blast-lamp as in Fig. 166. Bunsen states that the bottle should first be carefully heated between the shoulder and the neck, and the neck then drawn out by

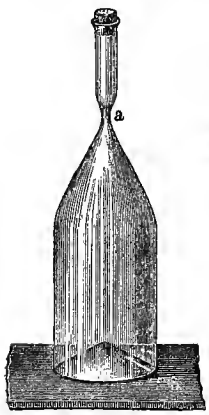

Fig. 166.

Fig. 167.

Fig. 168.

means of suitable tongs (Fig. 167). To fill the bottle with gas, the air in the bottle is sucked out through a small glass tube reaching to the bottom, this operation being repeated until the air originally in the bottle is completely replaced by gas from outside. Five or six full breaths are sufficient. It is self-evident that at each exhalation of the air sucked from the bottle one must step aside from the spot where the gas sample is being taken. The tightly stoppered bottle is then slightly warmed over a spirit-lamp, and equilibrium between the expanded air inside the bottle and the outside atmosphere is re-established by lifting the cork for a moment. After cooling, the diminished pressure inside the bottle prevents the blowing-out of the glass when the narrow neck is fused together. The fusion may conveniently be performed with the blow-pipe shown in Fig. 168. The small lamp (*a*) holds 3 grammes of oil and is connected with the blow-pipe by means of a flexible wire that carries a collar (*b*) through which the tip of the blow-pipe is inserted.

The cork *c* serves as a mouth-piece, by means of which the whole apparatus can be held and guided by the teeth alone. Thus both hands are left free, and the flame can still be moved in all directions, since the relative positions of the blow-pipe tip and the lamp remain the same, however the instrument be held.

The arrangement used by Hempel in his parallel researches "upon the composition of the atmosphere at different parts of the earth" is also a very convenient one. The air was collected in glass tubes of the form shown in Fig. 169. *d* is about 4 mm. thick; *a*, *b*, and *c*, only 1 mm. These tubes were heated in an air-bath in the laboratory to 200°, and were then exhausted with the mercury air-pump and fused together at *c*. By simply breaking the tube at *b*, it is filled instantly and with the greatest certainty by the gas in question. The tubes are then closed for a few moments with a rubber cap, and are melted together at *a* over a candle. The exhausting with the air-pump has the advantage of rendering one less dependent upon the care of the person who fills the tubes. If, however, it is desired to avoid this exhausting, the tubes are given the following form (Fig. 170). To fill such a tube, the gas to be examined is drawn through it and the tube is then fused together at *a* and *b* in a candle flame (Fig. 171).

Fig. 169.

Fig. 170.

Such tubes can be most safely shipped by packing them

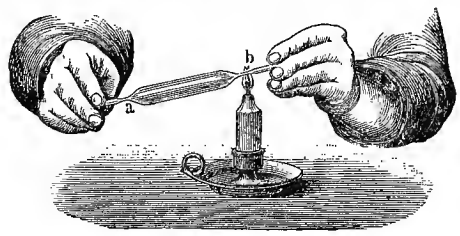

Fig. 171.

in sawdust in boxes which have a separate compartment for each tube. The boxes themselves are placed in a larger box filled with hay.

The tube last described is filled by the displacement of the air already contained therein. Naturally it is here presupposed that large amounts of gas are at one's disposal. If only a small quantity of gas is obtainable, the receiver must be filled with water or mercury, which is then displaced by the gas. Water can be used only when it is first saturated with the gases in question, as, for example, is always the case with the water of bubbling springs.

To collect gas from such springs as are directly accessible, the small apparatus proposed by Bunsen is used (Fig. 172).

This consists of a test-tube, *c*, of from 40 to 60 c.c. capacity, drawn out at *a* before the blast-lamp to the size of a fine straw, and connected air-tight with the funnel *b* by means of a well-fitting cork or a piece of vulcanized rubber tubing. Instead of the test-tube a small long-necked medicine bottle may be used, this being drawn out in the middle of the neck to a similar straw-like contraction. The apparatus is then filled with the water of the spring. This cannot be done without access of air, which would change the composition of the gases diffused through the spring water in the tube. Hence the inverted apparatus, with the mouth of the funnel upward, is lowered below the level of the spring, and, with a narrow tube reaching to the bottom of the test-tube, the water which in the first filling had come in contact with the air is sucked out until one is satisfied that it has been entirely replaced by other water from the spring. If now the gas of the spring is allowed to rise through the funnel into the test-tube thus filled, the purity of the sample is assured. If the rising bubbles stop in the neck

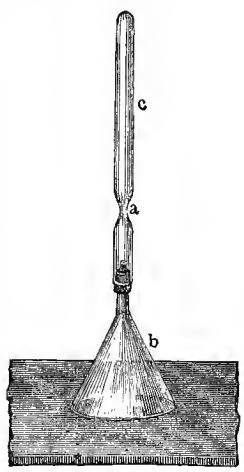

Fig. 172.

* These so-called medicine bottles are common glass bottles about 12 ctm. high. They were recommended by Bunsen because they can be found almost everywhere, even small village drug-stores having a supply of them.

of the funnel or at the contraction *a*, they can easily be made to ascend by tapping the edge of the funnel upon some hard substance. The apparatus is then placed in a small dish and removed from the spring, and the tube is melted together at *a*. This can easily be done with the blow-pipe, the moisture at the point *a* having first been driven away by warming.

For the determination of the volume and composition of the absorbed gases in liquids, the Tiemann and Preusse

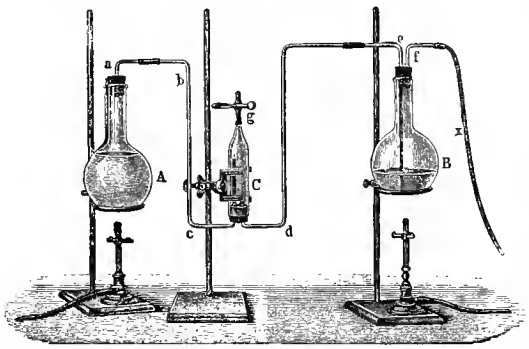

Fig. 173.

modification of Reichardt's apparatus[3] can be recommended (Fig. 173).

This consists of two flasks, *A* and *B*, each of about one litre capacity, and connected by tubes with the gas-collector *C*. The flask *A* is fitted with a perforated rubber stopper, in which is inserted the glass tube *a*, bent at a right angle and ending flush with the lower surface of the stopper. *a* is joined by a piece of rubber tubing to the tube *bc*, which in turn connects with the gas-collector *C*. *C* is held by a clamp, has a diameter of 35 mm., is about 300 mm. long, and at the upper end is drawn out to a short, narrow, and slightly bent tube which can be closed with the rubber tube and pinchcock *g*. In the lower end of *C* is a rubber stopper with two holes, through one of which the tube *bc*, projecting about 80 mm. into *C*, is inserted. Through the other opening passes the tube *d*, which extends only slightly beyond the stopper and connects *C* with the flask *B*. *B* has a double-bore rubber stopper carrying the tubes *e* and *f*. *e* ends about 10 mm. above the bottom of the flask, and above the stopper it is bent at a right angle and is connected with *d*. The tube *f*, which need not project below the stopper, carries a thin rubber tube (*x*), about one metre in length and provided with a mouth-piece. A pinchcock for closing the rubber tube between *a* and *b* is also needed.

The apparatus thus arranged is made ready for a determination by filling the flask *B* somewhat more than half full of boiled water, and removing the flask *A* by slipping the tube *a* out of the rubber connection; then, by blowing into the rubber tube *x*, water is driven over from the flask *B* into the gas-collector *C* and the adjoining tubes until the air is wholly displaced. The rubber tubes at *b* and *g* are now closed with pinchcocks. The flask *A* is then filled to the brim with distilled water, the stopper is inserted, water being thereby driven into the tube *a*, and the flask is again connected with *b*, the pinchcock being opened.

The water in *B* is now heated to gentle boiling, and that in *A* is allowed to boil somewhat more rapidly. The absorbed air is thus driven out, and the gases dissolved in the water which is in *A* and *C* collect in the upper part of *C*, from which they are removed by occasionally opening the pinchcock at *g* and blowing into the rubber tube *x*.

When, upon cooling the apparatus, the gases which have collected disappear, the heating of the flask *A* is discontinued, the pinchcock between *a* and *b* is closed, and *A* is disconnected and emptied. The water in *C* and *B* is now entirely free from absorbed gases, and air cannot enter from without because the liquid in *B* is kept continually boiling. The apparatus is now ready for a determination, which is made as follows:

The cooled flask *A*, whose capacity has been previously determined, is filled with the water to be examined, and the stopper is pressed in so far that the air in the tube *a* is completely driven out. *a* is then connected with *b*, care being taken that in so doing no air-bubbles are enclosed. The pinchcock between *a* and *b* is opened, and the water in *A* is heated to gentle boiling. The dissolved gases are hereby driven over into the gas-collector *C*. Steam is formed at the same time. The heating of the flask *A* must now be so regulated that the gas and steam evolved never drive out more than half the liquid in *C*; otherwise there is danger of gas-bubbles entering the tubes *d* and *e* and thus escaping.

After heating for about twenty minutes the flame under *A* is removed. In a few minutes the steam in *A* and *C* condenses, and water passes from *B* toward *C* and *A*. If a gas-bubble is observed in *A*, the flask *A* must again be heated and cooled in the manner just described. The operation is ended when the hot liquid flows back and completely fills *A*. The rubber tube *g* is then connected with a small tube which is filled with water or mercury, and the gas standing over the hot liquid in *C* is driven over into a eudiometer, gas burette, or gasometer by blowing into the tube *x* and opening the pinchcock *a*.

As it is difficult, and sometimes impossible, to completely remove the dissolved gases from water by boiling alone, it has been found advantageous to combine with the boiling of the water the use of the mercury air-pump. One of the best forms of apparatus thus far devised for the purpose has been recently described by Hoppe-Seyler[4] (Fig. 174).

A is first filled with mercury by raising *C*, the clamp *b* is closed, and the air in *B* is removed by opening *c* and lowering *E*, thus drawing most of the air in *B* over into the upper part of *D*. *c* is then closed and by raising *E* the air is driven out through *e*. Upon opening *c* some mercury will enter *B*, and the above procedure is repeated until all air has been removed from *B* and *D* and the tubes are filled with mercury. The water whose dissolved gases are to be examined, can then be drawn into *B* and *A* without coming into contact with the air. The water in *A* is then heated to boiling, the evolved gas collects in *B*, and, *b* having been closed, the gas can be

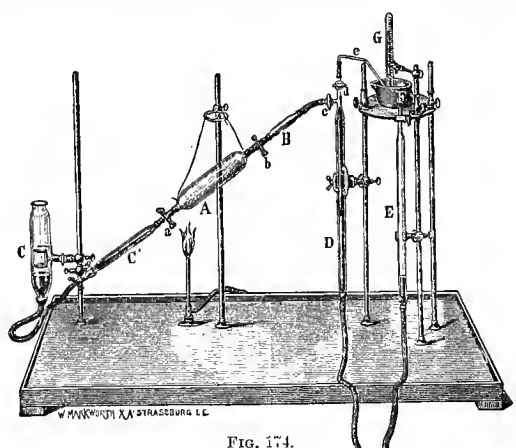

Fig. 174.

drawn over into *D* and transferred to the measuring tube *G* or any other desired apparatus.

The researches of Jacobsen and Pettersson have shown that it is impossible to remove the dissolved carbon dioxide from the water by boiling, and Hoppe-Seyler, in his description of the apparatus figured above, says that after forty boilings of a water containing carbon dioxide some of the gas still remained in the liquid. For these reasons it is best not to attempt to remove the gas

from the water, but to determine it while still in solution. One of the best methods for accomplishing this is one devised by Pettenkofer, which consists of precipitating the carbon dioxide dissolved in the water by adding a solution of calcium hydroxide of known strength, allowing the precipitate to settle, and then determining the excess of the calcium hydroxide in an aliquot portion of the clear supernatant liquid by titration with dilute oxalic acid. Litmus solution is used as the indicator. Sutton describes the method as follows :

"The following is the best method to be pursued for ordinary drinking-water not containing large quantities of carbon dioxide: 100 c.c. of the water is put into a flask with 3 c.c. of a strong solution of calcium chloride, and 2 c.c. of a saturated solution of ammonium chloride ; 45 c.c. of lime-water, the strength of which has been previously ascertained by means of decinormal acid, is then added, the flask well corked and put aside to settle. When the solution has fully subsided, take out 50 c.c. of the clear liquid with a pipette, and titrate this with

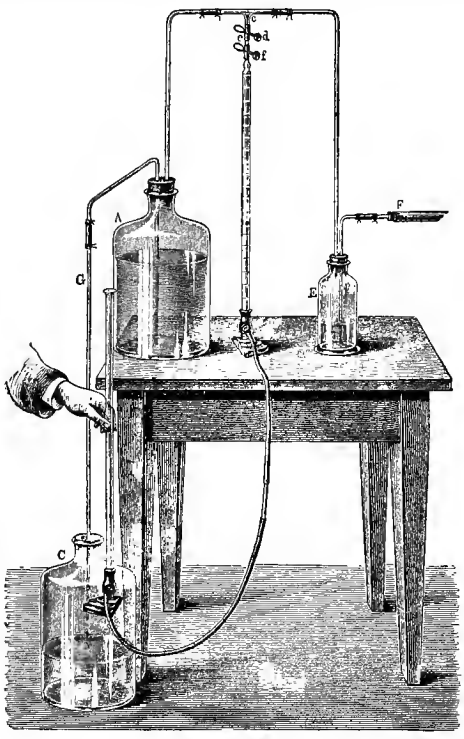

Fig. 175.

decinormal acid. The quantity required must be multiplied by three for the total lime solution, there being only 50 c.c. of the solution taken ; the number of cubic centimetres so found must be deducted from the original quantity required for the calcium hydroxide solution added ; the remainder multiplied by 0.0022 (the acid being decinormal) will give the weight of the carbonic acid existing free and as bicarbonate in the 100 c.c. of water.

"The addition of the calcium chloride and the ammonium chloride is made to prevent any irregularity which might arise from the presence of alkaline carbonates or sulphates; or of magnesia. If it be desired to ascertain the volume of the carbon dioxide from the weight, 1,000 c.c. of the gas at 0° C., and 760 mm. pressure, weigh, 1.96503 gramme."

If the gases to be collected have a pressure less than the prevailing atmospheric pressure, an aspirator must be used. The simplest form consists of two interchangeable bottles of equal size and the same width of neck.

Fig. 175 shows an arrangement which may be used when one wishes to take samples at the same time in a Hempel gas burette (see later). The water passes from the bottle *A* through the siphon *G* into *C*, and thereby draws the gas from the tube *F*. When *A* is empty, *C*, which is now full, is put in its place, the aspirating of the gas continuing as long as the samples are being taken. While the gas is being thus drawn from *F* into *A*, a sample for analysis may be at any time drawn off into the gas burette by lowering the level-tube, as shown in the figure, and opening the pinchcocks *d* and *f*.

When running water is at hand, the aspirating may be done by means of the ordinary glass or brass suction-pump attached to the faucet.

A gas can be best kept in the fused glass tubes already

Fig. 176.

described, but glass bulbs supplied with two glass stopcocks are also quite satisfactory (Fig. 176).

Metallic receivers should be used for analytical purposes only when the gas is to remain in them but a short time. They are, however, not easily broken, and are especially well adapted to the transport of large quantities of gas.

Rubber sacks should never be employed, since gas mixtures confined in them rapidly change in composition.

If large amounts of gas are to be collected and kept for analysis for a considerable length of time, the portions of gas taken for analysis must be displaced with mercury. It is utterly impracticable to use water for this purpose, for continual changes would take place, since the absorption varies with the pressure and temperature. A gasometer

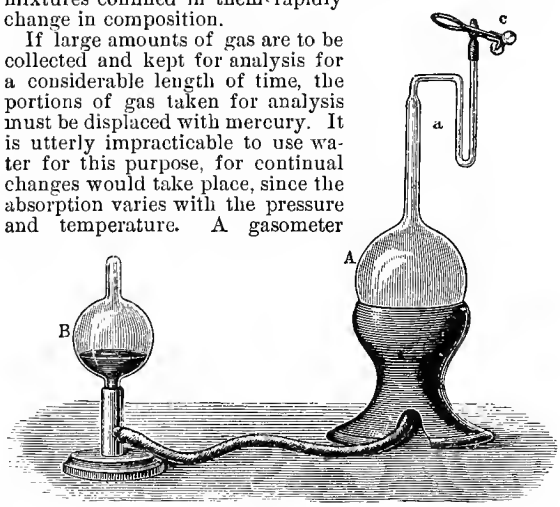

Fig. 177.

well adapted to keeping comparatively small volumes of gas is shown in Fig. 177.

The large glass bulb *A* serves to hold the gas. At the top it carries the bent capillary tube *a*, and at the bottom it is joined to the level-bulb *B* by a rubber tube. The capillary is closed by a rubber tube and pinchcock. The apparatus is first filled with mercury. By lowering or raising the level-bulb, gas can be drawn in or driven out as desired. If gases are to be kept for some time, the capillary tube *a* is filled with mercury by means of a little pipette inserted at *c*. This closes the bulb perfectly. In such an apparatus gases may be kept unchanged for an unlimited time.

Small glass bulbs (Fig. 178) are also very convenient. They are filled with gas in a mercury trough, and are then placed mouth downward in small porcelain crucibles containing mercury. The gas is taken out with the gas pipette to be described later.

Fig. 178.

(*b*) *The Apparatus.*—The amount of a gas may be determined by : 1, The direct measuring of its volume ; 2,

absorbing the gas with a solution of known strength, and then ascertaining by titration the amount of the solution which has been acted upon ; 3, absorbing the gas with a weighed amount of an absorbent, and then ascertaining the increase of weight ; 4, burning the gas, and determining the products by either volumetric or gravimetric methods.

Although isolated analyses of gases had been made before his time, Robert Bunsen[2] was the first to develop gas analysis as a distinct branch of analytical chemistry, and to devise methods by which gas mixtures could be examined with accuracy. The forms of apparatus and the methods which he introduced, and which have since been improved by Geppert,[7] have made possible, in the analysis of gases, an exactness that has perhaps never

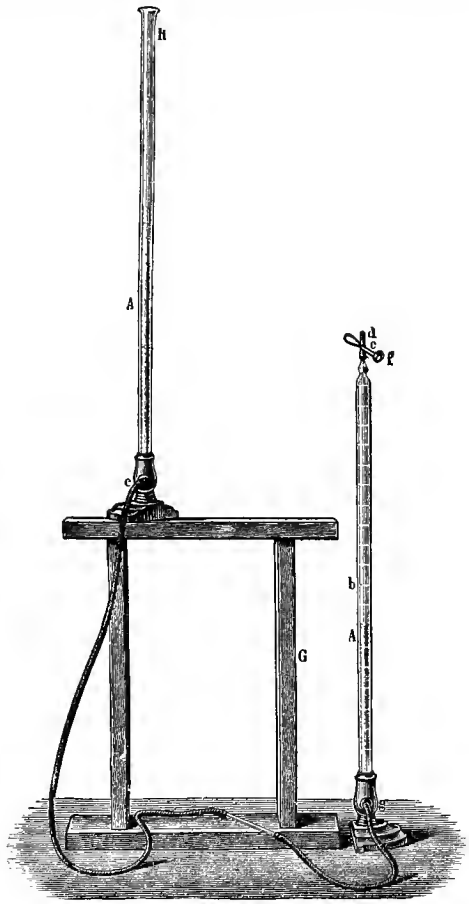

Fig. 179.

been exceeded by other procedures. But the apparatus used by both Bunsen and Geppert is cumbersome, and the analysis of a gas mixture of any complexity is a long and tedious operation, so that while Bunsen's methods have met with early and lasting approval, they have not found wide use among chemists.

With the growth of the great industrial processes in Europe, and especially in Germany, there arose a demand for analytic methods which, if not so exact as those of Bunsen, should be fairly accurate, simple, and rapid. This demand was met, with remarkable success, by Clemens Winkler, whose classical work upon qualitative and quantitative gas analysis[6] made the field of technical gas analysis as easily accessible as the other branches of analytical work developed by Rose, Mohr, Fresenius, and Plattner. In 1880 Walter Hempel published his "Neue Methode zur Analyse der Gase," and there described apparatus and methods remarkable for their exactness and ease of manipulation. The many improvements which Hempel has made in his methods since that time he has embodied in a second work, "Gasanalytische Methoden" (1890), from the English translation[1] of which many of the following descriptions are taken.

Hempel's Apparatus for Technical Gas Analysis. —*Gas Burettes.*—These are carefully graduated tubes in which the gases are measured.

A. The Simple Gas Burette (Fig. 179). This consists of two glass tubes, *A* and *A*, which are set in iron feet and are connected by a thin rubber tube about 120 ctm. long. To facilitate the cleaning of the burette the rubber tube is divided in the middle and the two ends joined by a piece of glass tubing.

Inside the feet the tubes are bent at right angles and conically drawn out. The end projecting from the iron is of about 4 mm. external diameter and is somewhat cor-

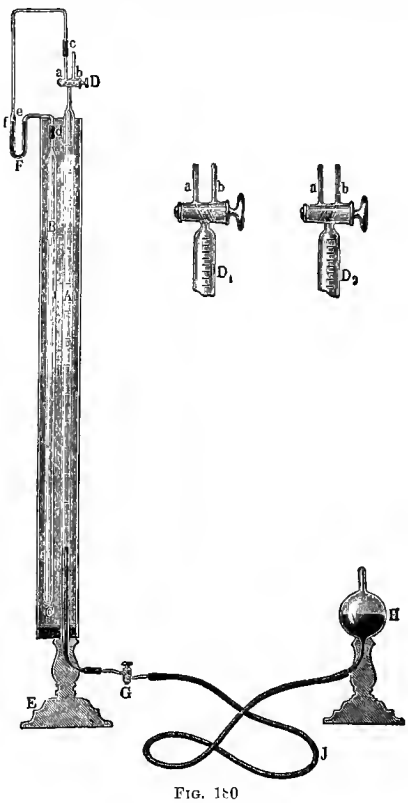

Fig. 180

rugated, so that a rubber tube may be tightly fastened to it by wire ligatures.

The measuring tube *b* ends at the top in a thick-walled tube, *c*, of from ½ to 1 mm. internal diameter and about 3 ctm. long. Over this a short piece of new black rubber tubing is wired on. The rubber tube is closed by a Mohr pinchcock, which is put on close to the end of the capillary. Notwithstanding the fact that readings cannot be made under the rubber tube, and that the pinchcock cannot always be put on above the tube in exactly the same position, no error results therefrom, since the glass tube *c* is very small.

The graduated measuring tube *b* contains 100 c.c., the lowest mark being slightly above the iron foot. The cubic centimetres are divided into fifths, and the numbers run both up and down. The other tube, which we will call the level-tube, is somewhat widened at the upper end, *h*, to facilitate the pouring in of liquids.

B. The Hempel-Pettersson Gas Burette, Independent of Changes in Temperature and Atmospheric Pressure (Fig.

180). The graduated measuring tube *A* contains 100 c.c. and is fastened into the heavy cast-iron foot *E*. The burette is closed at the top by an obliquely bored stopcock, which opens into the two capillary tubes *a* and *b*. The burette is connected by two short pieces of rubber tubing with the manometer *F* and the Pettersson correction tube *B*. This correction tube is a plain glass tube closed at the bottom and joined at *d* to the manometer *F* by a piece of rubber tubing. Both the burette and correction tube stand in a wide glass tube, *C*, filled with water. *C* is open at the top, and is closed at the bottom by a single-bore rubber stopper. The **U**-shaped part of the manometer tube *F* is about 6 mm. wide; from *e* to *e* it is capillary when mercury is used as the confiuing liquid, but when water is used this part is 3 mm. wide. The burette is connected by rubber tubing with the stopcock *G* and the level-bulb *H*.

Mercury, or water saturated with the gas to be analyzed, is used as confining liquid. If the gases are to be measured in a moist condition, as is generally advisable, a drop of water is introduced into the correction tube *B*.

Before using the apparatus for an analysis, the size of the space between *f* and *e* in the manometer tube must be determined once for all. This is done by drawing some air into the burette, and then bringing the three-way cock into the position D_1, so that the burette communicates with the manometer. By raising or lowering the level-bulb the enclosed gas can easily be brought to the pressure of the gas in the correction tube *B*. This is accomplished when the liquid stands at the same height in both sides of the **U**-tube of the manometer. The cock *G* is now closed, and the size of the gas volume is read off on the scale.

Upon again opening *G* and lowering the level-bulb, the liquid in the manometer tube may easily be drawn over as far as *e*; *D* is then closed again and another reading of the volume is taken, the gas being first brought to the pressure of the atmosphere by raising the level-bulb. The difference of the two readings gives the capacity of the tube between *f* and *e*. It is here presupposed that the air enclosed in *B* has the same pressure as the outside atmosphere. This can easily be brought about, for equilibrium is established by simply drawing the manometer tube at *d* out of the rubber connection.

Other slight changes of pressure need not be considered in making this measuremeut, since the volume of gas is itself very small.

This constant having been determined, the measurement of gases is made as follows:

Fill the burette completely with the confining liquid by raising the level-bulb, connect *b* by a capillary tube with the vessel containing the gas to be examined, and draw the gas into the burette. The stopcock must of course be in the position of D_2. To measure the gas, turn the cock into the position D_1, and by then raising or lowering the level-bulb bring the liquid in both sides of the manometer to the same level. The stopcock *G* is now closed and the reading is taken. The true volume is equal to that read off plus the correction-constant. After measuring, draw the gas out of the manometer-tube back into the burette.

The absorptions are made in gas pipettes described below, which are connected by means of capillary tubes with the tube *b*.

Absorption Pipettes.—A. The Simple Absorption Pipette for Liquid Reagents (Fig. 181). It consists of two large bulbs, *a* and *b*, joined by the tube *d*, and of a thick-walled glass tube, *e*, of ½ to 1 mm. internal diameter, and bent as shown in the figure.

This tube is called the *capillary tube*. The bulb *a* holds about 100 c.c., and *b* about 150 c.c., so that when 100 c.c. of gas is brought into *b* sufficient space for the absorbing liquid will remain. To protect the pipette from being broken and to facilitate its manipulation, it is screwed to a wooden or preferably an iron standard. On account of the different behavior of wood and glass or iron toward changes of temperature and atmospheric moisture, it is advisable to fasten the glass at only three places by means of metal bands and sealing-wax, the capillary tube being allowed to project from 2 to 3 ctm. above the frame.

A short piece of rubber tubing is wired on to the free end of the capillary. The distance *h* must be greater

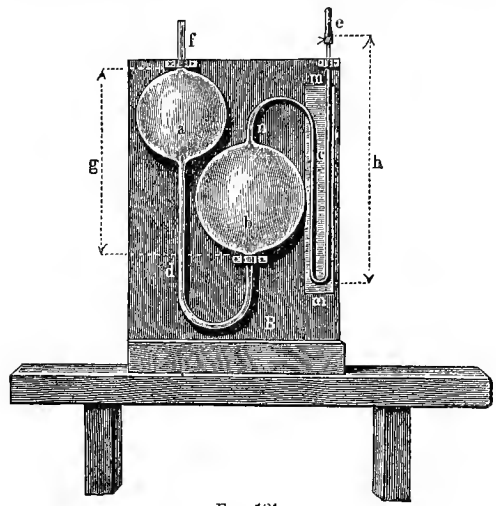

Fig. 181.

than *g*, so that it may be possible to enclose a gas between two columns of liquid in the pipette. If a wooden stand is used, a white porcelain plate is set in at *m* to render the liquid in the capillary tube more distinctly visible, but if the stand be of iron, as shown in Fig. 182, no plate is necessary.

B. The Simple Absorption Pipette for Solid and Liquid Reagents. The only difference between this and the simple pipette is that in place of the bulb *b* there is inserted a cylindrical bulb provided with a neck through which solid reagents can be introduced (Fig. 182). The neck can be closed by a cork or rubber stopper, held in place by a wire. Or a glass tube closed at the top, and over which a rubber ring, cut from a rubber tube is drawn, may be used (see cut).

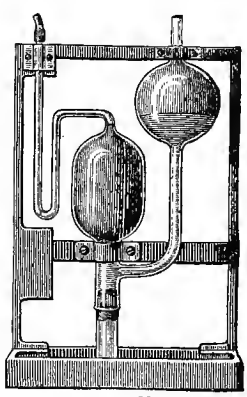

Fig. 182.

Double Absorption Pipettes. Reagents which are acted upon by oxygen, *i.e.*, potassium pyrogallate, cuprous chloride, ferrous salts, etc., cannot, of course, be kept in the above form of pipette, since the reagent in *a* would become inactive in a short time through contact with the air. To avoid this difficulty, Hempel devised

C. The Double Absorption Pipette (Fig. 183). The reagent is contained in the bulbs *a* and *b*. The bulbs *c* and *d* contain water and prevent all access of air to the reagent. *a* is of about 150 c.c. capacity, and *b*, *c*, and *d* contain each about 100 c.c. The bulbs are connected by the bent tubes *e*, *f*, and *g*, and end in the bent capillary tube *k*.

To permit of the use of solid reagents in this double pipette, it may be modified as was the simple pipette.

D. The Double Absorption Pipette for Solid and Liquid Reagents (Fig. 183). The solid reagent is introduced into the cylindrical bulb *a* through the neck, a hole being bored through the wooden base opposite the neck to permit of this.

The double pipettes are prepared for use as follows: If a solid substance is to be used, the last-named pipette (Fig. 183) is employed and the solid is introduced into *a* through the neck. The cork is then inserted and wired in. The

method of filling is now the same for either of the double pipettes. Pour some water through *m* into the bulb *d* until *g* is full. Insert into the rubber tube *l* a funnel, and fill the funnel with the liquid reagent to be employed. Attach to *m* a piece of rubber gas-tubing about a foot and a half long, and suck with the mouth. The rubber tube may, of course, be connected with the aspirator, but in that case care must be taken that the suction

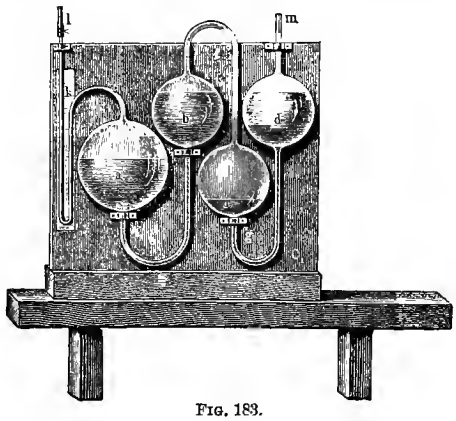

Fig. 183.

does not become strong enough to crush the bulbs. After there has been drawn into *a* and *b* sufficient reagent to fill *a*, the bulb *d* is nearly filled with water, and the gas remaining in *a* is driven out through the capillary by blowing into *m*. The pipette is now closed at *l*, and shaken for some time to remove from the bulb *b* the gases absorbable by the reagent. After any gas-bubbles which may now be in *a* have been driven out, suction is applied at *m*, and so much gas is sucked out of the bulb *b* that the liquid in *d* will enter and completely fill *c*. If the water first poured in is not sufficient, more must be added from time to time.

In pipettes thus prepared the tubes *k* and *e* and the bulb *a* are filled with the absorbent, the space from *b* to *f* with a gas free from oxygen, *c* and *g* with water, and *d* with air (Fig. 184). While the reagent in the simple

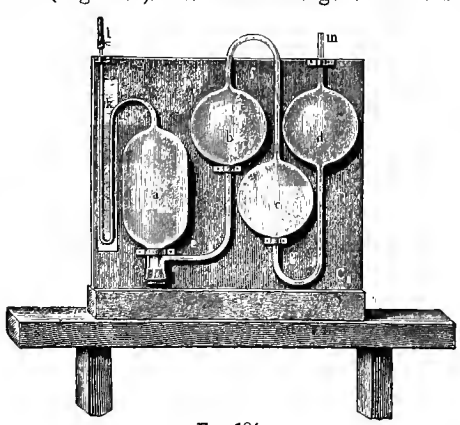

Fig. 184.

pipette may be considered to be saturated with gas only when it is kept in continual use, that in the double pipette, on the contrary, remains saturated for an exceptionally long time, since the diffusion must take place through the confining 100 c.c. of water and through the narrow tube *g*. The error caused by this theoretical possibility may be wholly disregarded in using the pipette. When a new filling of the pipette is necessary, the reagent may easily be driven out by inverting the pipette and blowing into *l*.

Manipulation of the Hempel Burette and Pipettes.— To analyze a gas with the apparatus described, the burette is filled with distilled water which has been previously saturated, by shaking, with the gas in question. The saturating of liquids is best done in a flask half filled with the same, a rapid stream of gas being led through the liquid, and the flask vigorously shaken. If simple pipettes are used, these are so filled with the absorbent that the bulb *a* remains empty. The absorbent also must be saturated, by shaking, with the gases which are but slightly soluble in it.

In technical work, where the same analyses are repeatedly made, the absorbent is kept saturated through continual use.

Before beginning the analysis pour into the level-tube of the gas burette (Fig. 185) enough water to fill the measuring tube *b* and the connecting rubber tube, taking care to drive all air out of the latter by suitably raising and lowering the tubes. Then join the burette to the vessel containing the gas by means of a glass or rubber

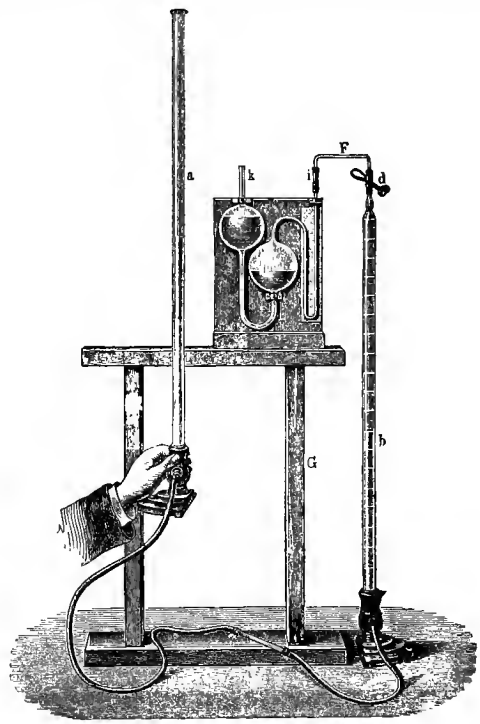

Fig. 185.

tube filled with water. (This connecting tube can be easily filled with water by raising the level-tube).

To fill the burette with the gas to be examined, place the level-tube on the floor and open the pinchcock *f*. The water will now flow into the level-tube and the gas will be drawn into the burette. When *b* is filled with the gas, close the pinchcock *f*, disconnect *b* from the gas-holder, and after the liquid has run down from the walls of the burette, take up the tubes by the iron feet and by raising or lowering bring the water in the tube to the same level. The gas is now under atmospheric pressure and its volume is read off. To measure off exactly 100 c.c., bring somewhat more than 100 c.c. of the gas into the burette, close the latter with the pinchcock, and let the water run down. Now compress the gas to less than 100 c.c. by raising the level-tube, close the rubber tube at *g* with the thumb and first finger of the left hand, set the level-tube on the table, and raising the burette in the right hand to the level of the eyes, carefully open the rubber tube and let the water run back until the meniscus stands at the 100 c.c. mark. Keeping the rubber tube still compressed, open the pinchcock for a moment; the excess of

gas will escape, and there remains in the burette exactly 100 c.c. of gas under atmospheric pressure.

If the pipettes have the temperature of the room, as can easily be ascertained by introducing a thermometer at *k* (Fig. 185), the apparatus is now arranged as there shown.

The pipette is placed on the wooden stand *G* and is connected with the burette by the capillary tube *F*, which is a piece of thermometer tubing of about 0.5 mm. internal diameter.

To avoid the enclosing of air-bubbles *F* is first inserted in *d*, the level-tube *a* is raised, and the pinchcock opened for a moment. *F* is, in this way, filled completely with water. Then the rubber tube *i* of the pipette is squeezed between the thumb and the first finger of the right hand, and while thus compressed and free from air the capillary connecting tube is inserted.

Upon raising the level-tube *a* and opening the pinchcock the gas passes through the connecting tube into the absorption pipette. Any small air-bubbles which may have been enclosed when *F* was inserted into *i* are, at the beginning, separated from the gas by the water in *F*. If these bubbles do not take up more than 5 to 10 mm. space in the capillary of the pipette, they may be disregarded, since the error arising therefrom is about 0.03 c.c. If the bubbles are larger, although with a little cleverness this may always be avoided, the gas is brought back into the burette by lowering the level-tube, and the operation is repeated.

When the gas has passed over into the pipette, about ½ c.c. of water is allowed to follow, this water serving to rinse the capillary and to free it sufficiently from the absorbing liquid which it previously contained. The gas is now enclosed between two columns of liquid, the absorbent on the one side, and the water in the capillary on the other.

The pinchcocks at *d* and *i* (the latter is not shown in the figure), are closed, the pipette is disconnected by drawing *F* out of *i*, and by shaking the pipette horizontally the absorption of the gas is effected.

The burette and pipette are then reconnected, the level-tube is placed on the floor, and the gas is brought back into the burette, care being taken that the absorbing liquid does not pass farther than the bend in *F* above *d*. The pinchcock *d* is closed, the pipette removed, and the reading of the remaining volume is made as before described.

The manipulation of the pipettes filled with solid absorbents is still simpler, for in this case no shaking is necessary, because of the large surface between the solid and the gas. On this account, also, the apparatus need not be disconnected.

A separate pipette is used for each absorbent, and aside from the economy of reagents the frequent cleaning of the apparatus is thus avoided. An especial advantage is, further, the complete assurance that no loss can take place through ill-fitting glass or rubber stopcocks while the gas is in the pipette or when the pipette is vigorously shaken, and that without fear of error due to the taking up of gases not chemically absorbable, large amounts of reagent may be used, and the work be thereby greatly shortened. After using, the pipettes are closed at *i* with a piece of glass rod, and at *k* with a small cork. It is advisable to record the number of cubic centimetres of gas which the reagent has absorbed. When the wooden support for the pipette is used, this record is kept upon a piece of paper fastened to the back. If the iron support shown in Fig. 182 is in use, a ground glass plate fastened between the sides of the base may be conveniently employed for the purpose. If the absorbing power of the reagent be known, waste may be avoided, and with one filling of the pipette several hundred analyses (the number depending upon the nature of the gases examined) may be made, with certainty throughout as to the efficiency of the absorbent.

If the work has not been carelessly done, the gas burette stands ready for the next analysis. If, on the other hand, reagents have been allowed to enter the burette, it must be cleansed, its simple construction rendering this quite easy.

With the Hempel apparatus just described, analysis of gas mixtures may be made with great rapidity and considerable accuracy, the exactness being increased by the use of the Hempel-Pettersson burette. But as the unavoidable error in measuring the gas volume in the burette amounts to about 0.1 c.c., *i.e.*, to 0.1 per cent., it is clear that if greater accuracy is desired certain modifications in the method become necessary. Hempel has devised an apparatus with which results agreeing as closely as those of Bunsen and Geppert may easily be obtained, and as his method is more rapid and the apparatus simple in form and easy to handle, a brief description of it is here given.

Hempel's Apparatus for Very Exact Gas Analysis.—Usually in analytical work the gases are measured under constant (atmospheric) pressure, the observed

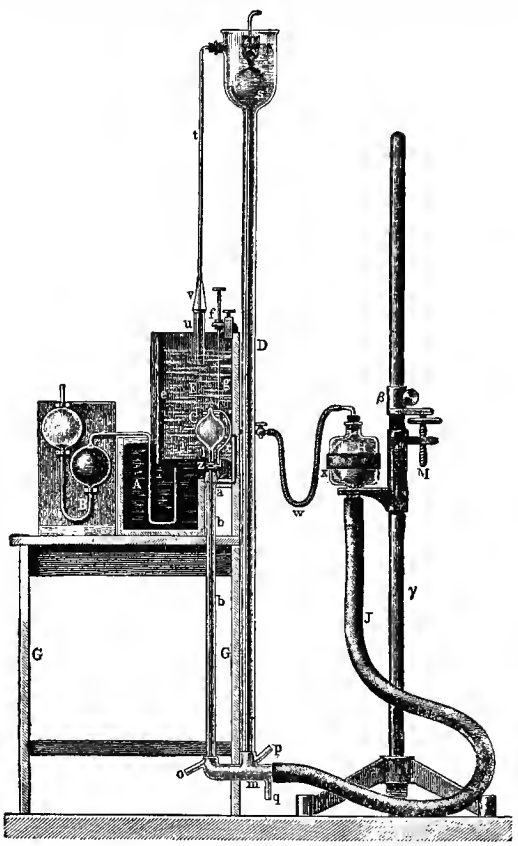

Fig. 186.

changes in the volume, as each constituent is absorbed, giving the percentage composition of the gas. In the method about to be described the measurements are, however, made under constant volume and varying pressure. That is, after the absorption of each constituent the gas is expanded to exactly the volume which it occupied in the beginning, and the change in the pressure which it exerts is read off on a graduated barometer tube.

Following Boyle's law, the values so found bear the same proportion to one another as do gas volumes under the same pressure, and hence give the percentage results directly. If the gases are saturated with moisture when measured, corrections for the tension of aqueous vapor and for barometic pressure are unnecessary.

The gases are expanded to a certain volume in small glass bulbs, which can easily be brought into communication with a barometer. The expanding is done by lowering a movable vessel filled with mercury. The pressure exerted by the gas is then read off on the barom-

eter scale. The temperature is kept constant throughout by surrounding all parts of the apparatus with running water. The absorptions are made in the gas pipettes to be described later.

Description of the Apparatus.—Fig. 186 gives a sectional view of the apparatus. The iron mercury-trough *A* is fastened to the wooden stand *G*, and is connected with the graduated barometer tube *D* by the iron tube *b*. The barometer tube is connected at *m*, by means of a rubber tube, *J*, with the level-bulb *H*. The upper part of the mercury-trough consists of the reservoir *E*, whose overflow-tube (this is not given in the drawing) can be connected with a barrel by means of glass or rubber tubes.

The sides of the water reservoir *E* are glass panes, one of which, *c*, extends only so deep into the mercury as to leave it easily possible to bring under it the end of the capillary tube of the pipette *B*. The measuring bulb *C* serves to hold the gas. The tubes *b* and *D* are surrounded with larger glass tubes, and the rubber tube *J* is double, so that *b*, *D*, and *J* may be cooled with water. By means of a glass tube with three arms (this tube does not appear in the figure) water is admitted simultaneously through the tubes *o*, *p*, and *q* when the apparatus is in use. *o*, *p*, and *q* are joined to the three-arm tube by rubber tubes supplied with glass stopcocks. A part of the water enters at *o*, surrounds *b*, and enters the water reservoir *E* through a small canal, *r*. The water entering at *p* surrounds the barometer tube *D* and its bulb *s*, and runs through a side opening and the tube *t* into *E*. To prevent the spattering caused by the air-bubbles drawn along with the water, a wider tube, *u*, is hung upon *t* by means of the thread *v*. A third stream of water entering at *q* passes through the outer rubber tube of *J*, and through the double-walled level-bulb and the rubber tube *w* into *E*.

The outer wall of the level-bulb is simply made by joining together the ends of two broken bottles by the rubber band *x*. The rubber tube *w* is joined to the bulb by means of a cork and a bent-glass tube.

By this arrangement it is possible to keep all parts of the apparatus at the same temperature.

The Gas Pipettes for the Exact Apparatus.—They consist of two bulbs, *a* and *b* (Fig. 187) of the same size, joined together by the tube *c* and ending in the bent capillary tube *d*. A very small-bore thermometer tube is used as the capillary, thus making it easy to avoid the introduction of absorbent into the measuring bulb or the remaining of any considerable quantity of gas in the pipette.

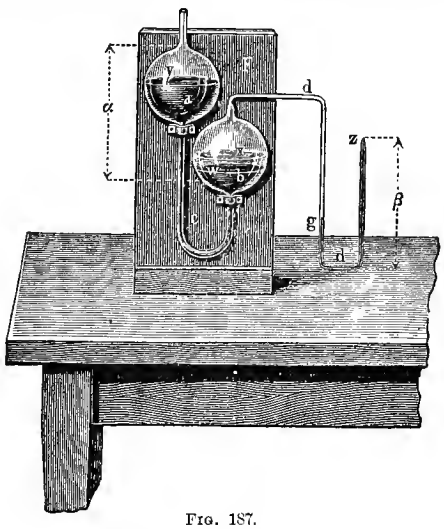

Fig. 187.

Gases move rapidly in capillary tubes, but liquids, especially concentrated solutions of salts, move very slowly; hence it is easily possible to bring the gas residue in the pipette to less than $\frac{1}{1000}$ of a cubic centimetre without danger of the absorbent entering the measuring bulb.

The pipettes must be so made that the distance *a* (Fig. 187) is only as large as or smaller than β: the capillary must be bent close to the bulb *b*. The pipettes are fastened to the wooden standard in such a manner that the capillary *d* comes to within a few millimetres of the bottom of the mercury-trough when the pipette is placed in the position shown in Fig. 186.

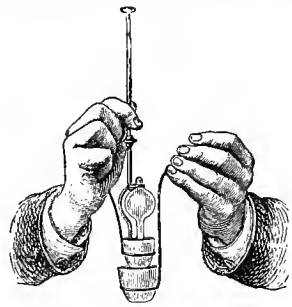

Fig. 188.

Fig. 189.

The bulbs of the pipettes must be considerably larger than the volume of the gas to be brought into them. The inconvenience of carefully cleaning the pipette after the absorption is avoided by using a special pipette for each reagent. Pipettes of very different sizes are employed, the sizes depending naturally upon the dimension of the measuring bulbs.

Manipulation.—One of the pipettes is filled with mercury, and the gas to be analyzed is passed into the pipette through the capillary. A little mercury is allowed to follow the gas and fill the capillary from *g* to *z* (Fig. 187). The gas is thus confined between two surfaces of mercury, *g* and *w*.

If the samples of gas have been collected in the glass tubes shown in Figs. 169 or 170, the tubes are opened in a small mercury-trough by breaking off the immersed end of the tube with pliers. A small crucible is then slipped under the tube, and the tube is lifted out and placed in a cylinder containing mercury. The capillary of a gas pipette filled with mercury is then lowered beneath the surface of the mercury and introduced into the tube containing the gas, and the gas is drawn over into the pipette by sucking with the mouth upon a rubber tube attached to the open end tube of the bulb *a*. One of the measuring bulbs (*C*, Fig. 186) with its iron holder is then cleaned and dried, and is brought into the mercury-trough of the apparatus by placing it in two porcelain crucibles, one within the other (see Fig. 188), and filling these with mercury. If these are then lowered through the cooling water of the trough into the mercury, and the longer crucible removed by lowering it still further, the measuring bulb may now be lifted out of the small crucible under the surface of the mercury without a trace of water entering it. If only one crucible is used, water may easily get into the bulb, the probable cause being surface adhesion. The instrument shown in Fig. 189 is then lowered into the mercury-trough *A* (Fig. 186), the end of its tube is introduced into the measuring bulb, and the air in the latter is sucked out completely.

The pipette containing the gas is now placed as shown in Fig. 186, the measuring bulb, which now is full of mercury, is lowered over the end of the capillary of the pipette, and, by blowing into the open end of the pipette, some of the gas is driven over into the measuring bulb. The pipette is removed and the measuring bulb is placed over the end of the tube *b* (see Fig. 186), and, by means of the screw at *f*, is pressed down tightly upon the rubber stopper surrounding the end of *b*. The level-bulb is lowered until the meniscus of the mercury column at *l* exactly coincides with the cross-hair of a magnifying-

glass fastened to the mercury trough. (This magnifier does not appear in the figure.) The reading of the barometer tube, which is best done by means of a telescope, gives then directly the pressure of the gas ; this pressure is obviously independent of barometric changes, since the barometer vacuum is closed with mercury. If the gas being measured is saturated with moisture, the correction for the tension of aqueous vapor is unnecessary,

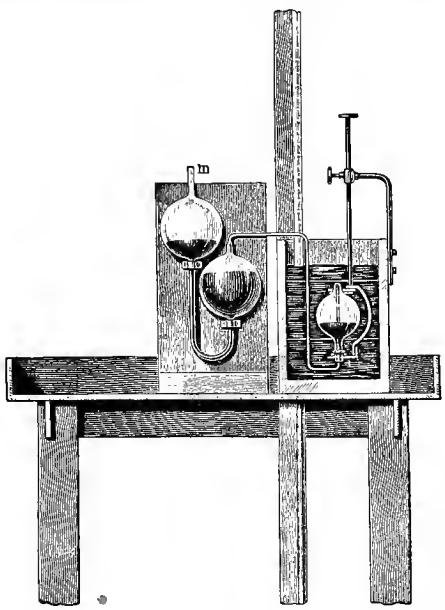

Fig. 190.

because there is in the bulb of the barometer aqueous vapor which at the same temperature exercises the same pressure in an opposite direction.

The exact adjustment is made with the micrometer screw of the level-bulb, and the reading on the scale is then immediately made with the telescope. It is advisable to repeat both the adjustment and the reading.

Into one of the pipettes filled with mercury there is now introduced, through the capillary, a suitable amount (about two cubic centimetres) of the desired reagent. The measuring bulb is removed from the end of the barometer tube, and the bulb and pipette are brought into the position shown in Fig. 190.

The gas is drawn into the pipette by sucking with the mouth on a rubber tube attached to *m*. The suction is discontinued at the moment when the mercury begins to flow from the capillary into the bulb of the pipette.

The pipette then contains (see Fig. 187) mercury from *v* to *w*, absorbent from *w* to *x*, gas from *x* to *g*, and mercury from *g* to *z*, so that the pipette, after it is taken out of the mercury trough, may be vigorously shaken and a rapid absorption effected.

To drive the gas from the pipette back again into the measuring bulb, the apparatus is brought into the position shown in Fig. 191.

One must at first blow into the pipette at *m* to set the gas in motion; when it has once started, the mercury in the measuring bulb acts with an aspirating effect, so that the gas passes over of itself. At the moment when the absorbent has risen to about one centimetre from the end of the capillary in the measuring bulb, the capillary is lowered under the mercury and mercury is drawn into the capillary by sucking on the rubber tube attached to *m*. In this manner the entering of the reagent into the measuring bulb may be avoided with certainty.

If a gas thread about 1 ctm. long remains in the capillary, this corresponds to approximately 0.001 c.c. of gas, since the total 35 ctm. length of the capillary has a volume, determined by weighing the mercury which it holds, of 0.038 c.c. Hence from this source no appreciable error arises.

The measuring bulb is again brought into the position shown in Fig. 186, the mercury in the bulb adjusted exactly at *e* by raising or lowering the level-bulb, and the variation in pressure is read off on the graduated barometer tube *D*. As the original pressure is to the change in pressure as the original volume is to the volume absorbed, the per cent. of the absorbed constituent is easily calculated.

The other necessary measurements, absorptions, and explosions now follow, their order being determined by the nature of the gas.

The Quantitative Analysis of a Gas Mixture.— Before proceeding with the quantitative determination of the various gases in any gas mixture, it is, of course, necessary to know what gases are present. If this is not known, a qualitative analysis of the sample must first be made. As a description of the methods of qualitative gas analysis would take too much space, and as the constituents of mixtures with which we purpose here to deal are usually known, the reader is referred for information upon qualitative gas analysis to the exhaustive treatise of Clemens Winkler.[6]

Assuming that it is known what gases are present, the remainder of the article will be devoted to descriptions of the various methods by which the amounts of these gases may be ascertained.

In the analysis of a mixture of gases the usual procedure is to measure off a definite volume of the gas, and then, with the apparatus already described, to absorb

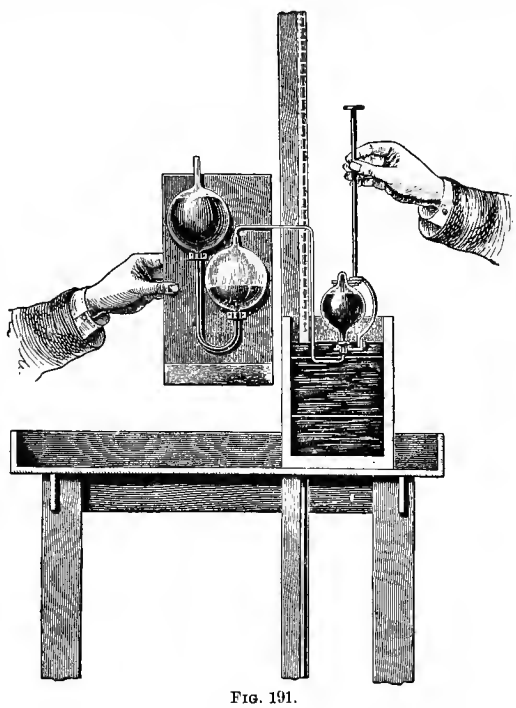

Fig. 191.

one after another of the gases present, the diminution in the volume of the gas after each absorption showing the amount of the absorbed constituent which was present in the original mixture. Those gases which cannot be absorbed, such as certain hydrocarbons and nitrogen, will still remain after the absorption of the others. The hydrocarbons are usually determined by burning them with oxygen or air, and the gas now remaining is nitrogen.

The absorbable gases whose determination is most frequently called for are:

Gases.	Absorbable by
Carbon dioxide (CO_2).	Potassium hydroxide or barium hydroxide.
Oxygen (O).	Alkaline pyrogallol or phosphorus.
The "heavy hydrocarbons," as ethylene, propylene, etc.	Fuming sulphuric acid.
Carbon monoxide (CO).	Cuprous chloride.
Hydrogen (H).	Palladium sponge.

The solutions just mentioned may be prepared as follows:

Potassium Hydroxide Solution.—One part of commercial caustic potash is dissolved in two parts of water.

This solution is put into the simple pipette for solid and liquid reagents (Fig. 182), the cylindrical part *b*, being first closely filled with very short rolls of iron-wire gauze. The gauze has a mesh of 1 to 2 mm., and the rolls are from 1 to 2 ctm. long and about 5 mm. thick.

When the per cent. of carbon dioxide is not too high it can be completely absorbed by simply passing the gas once into the pipette. The complete manipulation does not take one minute.

Small quantities of carbon dioxide are best determined by absorption in a solution of barium hydroxide and titration with oxalic acid (see Analysis of Air).

Alkaline Pyrogallol (Potassium Pyrogallate).—Dissolve 150 grammes of potassium hydroxide in 100 c.c. of water and allow it to stand until the insoluble residue has settled. Five grammes of pyrogallol (pyrogallic acid) dissolved in 15 c.c. of water is then mixed with four-fifths of the caustic potash solution, only the clear portion of the latter being used for this purpose. In the Hempel apparatus for technical analysis this solution is used in the pipette shown in Fig. 183. The 15 c.c. of the alkaline pyrogallol should first be run into the bulb *a* through the capillary, and then the caustic potash solution be run in after it. If there is not enough solution to fill the bulb *a*, more of the two solutions, in their proper proportions, should be added. The solution must not be diluted with water.

The absorptions should not be carried on at a temperature under 15° C., for it has been observed that the potassium pyrogallate used for absorption is very much less active at a temperature under 7° C. At a temperature of 15° C. or higher the last trace of oxygen can be removed with certainty in the space of three minutes by shaking with the solution of potassium pyrogallate, while at lower temperatures the absorption is not complete after six minutes; moreover, the liquid begins to foam, and this, in exact determinations, is very troublesome.

A solution prepared as above gives off no carbon monoxide during the absorption, or at the most only such slight traces that the error thus caused comes within the limit of error of the readings.

Fuming Sulphuric Acid.—The sulphuric acid used should be so concentrated that when the temperature is slightly lowered, crystals of pyro-sulphuric acid will separate. The acid is used in a Hempel pipette which has above the large bulb *b*, Fig. 181, a small bulb filled with glass beads which serve to give to the sulphuric acid the largest possible surface. With this arrangement the complete absorption of the heavy hydrocarbons, and of ethylene in particular, is effected by passing the gas into the pipette but once.

In this reaction some sulphur dioxide is usually formed, and, moreover, the vapor of fuming sulphuric acid has a very high tension, so that the gas residue, before being measured, must be freed from the acid vapors in the caustic potash pipette, a single passage of the gas into the pipette being also here sufficient.

To avoid having the rubber connections between the pipette and burette attacked by the fuming sulphuric acid, the apparatus is so put together that the sulphuric acid does not quite fill the capillary of the pipette, and the connecting capillary is allowed to remain empty; the short rubber tube of the burette is also freed from liquid by means of a narrow-tipped suction pipette, any reagent remaining in the rubber tube being first washed out by water with the same pipette. If care be taken that the sulphuric acid is stopped, after the absorption, at the same point in the capillary at which it stood when the burette and pipette were first put together, then the small volume of air contained in the empty capillary tubes in the beginning causes, of course, no error in the determination of the heavy hydrocarbons or other gases, with the exception of nitrogen. In the nitrogen determination allowance may be made for this air volume, but as each centimetre of the empty capillary corresponds to only 0.008 c.c., this value falls below the limit of the usual unavoidable experimental errors.

After the absorption the rubber tube is taken off from the pipette, and the capillary and the larger tube are closed air-tight by little glass caps, which are pushed over narrow rubber rings placed upon the tubes.

Cuprous Chloride.—This solution may be conveniently prepared as follows: Twenty-five parts of crystallized copper sulphate, and 12 parts of sodium chloride are put into 50 parts of water, which is then heated until all dissolves. Some sodium sulphate may separate as a white powder. Filter it off and add 100 parts of concentrated hydrochloric acid and 13 parts of copper turnings (also a few pieces of platinum foil to hasten the solution of the copper) and boil until decolorized. Pour the solution into a glass-stoppered bottle and keep tightly stoppered until needed.

Palladium Sponge.—Finely divided metallic palladium is heated, in portions of about one gramme at a time, nearly to redness upon the cover of a platinum crucible. The platinum cover is slowly lifted out of the flame, the palladium, as it cools, becoming covered with a coating of palladious oxide. About four grammes of the sponge thus prepared is placed in the **U**-tube shown in Fig. 193.

To illustrate the procedure in an analysis of a gas mixture with the Hempel apparatus the analysis of a sample of illuminating gas is given.

First of all, the water with which the burette is to be filled must be saturated with the gas, as described above. The carbon dioxide is first absorbed with caustic potash, then the heavy hydrocarbons with fuming sulphuric acid, then oxygen with alkaline pyrogallol, and lastly carbon monoxide with the cuprous chloride solution. The residue, which consists of methane, hydrogen, and nitrogen, is measured, and is then led back into the cuprous chloride pipette, and a portion is taken for the explosion analysis.

With ordinary illuminating gas about 12 c.c. of the residue suffice for the explosion.

These 12 c.c. are measured off exactly in the gas burette, and enough air is drawn in to bring the mixture to about 100 c.c. In all these measurements the running down of the liquid must be most carefully waited for, because the amount of gas taken is so small that any errors that may be made are greatly multiplied. Three minutes is a sufficient time to wait for the water to run down the sides of the burette, but whatever brief interval is taken it should be the same for each measurement. To insure uniformity in this respect, a three-minute sand-glass may be used with advantage.

The gas mixture is now burned in the explosion pipette (Fig. 192).

This consists of the thick-walled explosion-bulb *a*, and the level-bulb *b*, which are joined together by a wrapped piece of rubber tubing. At *e* two fine platinum wires are fused into the explosion pipette, the ends of the wires being about 2 mm. apart. At *d* is a glass stopcock, and the pipette terminates in the capillary *e*, whose end is closed by a short piece of rubber tubing and a pinch-cock. In general the pipettes and burettes for technical gas analysis are filled with aqueous solutions, but the explosion pipette is filled with mercury. By using mercury as confining liquid during the explosion it is possible to afterward determine the carbon dioxide formed by the combustion. If the explosion is made over water, a subsequent measuring of the carbon dioxide formed is inadmissible, because the pressure in the pipette is so high during the explosion that considerable quantities of carbon dioxide are absorbed by the water. By explod-

ing over mercury very satisfactory results are obtained, even if the carbon dioxide is afterward measured in a burette which is filled with water.

After the gas is burned in the explosion pipette it is transferred to the burette and the total contraction is measured. Then the carbon dioxide is absorbed with potassium hydroxide, and finally the oxygen in excess is absorbed with phosphorus. The last determination is made merely to be sure that a sufficient excess of oxygen was present in the combustion.

The manipulation and the results obtained in an analysis of a sample of illuminating gas with the Hempel apparatus were as follows:

Exactly 100 c.c. of the gas was measured off in the burette.

Passed into caustic potash pipette and drawn directly back into the burette; measured after three minutes. Measurement gave 4.1 c.c.; hence there was present 4.1 c.c. or per cent. carbon dioxide.

Burette now connected by means of a dry piece of rubber tube and a dry capillary with the pipette containing fuming sulphuric acid. Gas driven over and drawn back at once into the burette. Gas now passed again into caustic potash pipette, and after being drawn back into the burette and allowed to stand three minutes, again measured. The measurement gave 8.4 c.c.; hence there

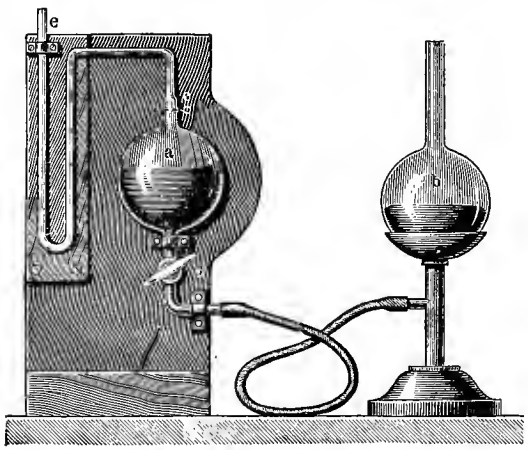

FIG. 192.

were $8.4 - 4.1 = 4.3$ c.c. or 4.3 per cent. of heavy hydrocarbons present.

The gas now passed into the double pipette containing alkaline pyrogallol, the burette and pipette closed with pinchcocks, the pipette disconnected and shaken for three minutes. Then connected with the burette again, drawn over and measured at the end of three minutes. Reading gave 8.4 c.c.; hence no oxygen was present.

The gas was then passed into the pipette containing cuprous chloride, and was shaken for three minutes. Drawn back into the burette and measured after three minutes; the reading was 18 c.c.; hence there was 18 c.c. $- 8.4 = 9.6$ c.c. or per cent. carbon monoxide present.

The remaining 82 c.c. of gas was then passed back into the cuprous chloride pipette, and the pipette was closed with an ordinary pinchcock.

The water in the burette is poured out, the burette washed with hydrochloric acid and then with distilled water, and then filled with water which is saturated, not with illuminating gas, but with air.

Twelve to fifteen c.c. of the gas residue is now measured off into the burette. In this case 13.2 c.c. was taken.

So much air is then drawn in that the total volume of the gas residue taken and the air amounts to about 100 c.c. In this case it was 99.6 c.c.

This mixture is now brought into the explosion pipette filled with mercury, care being taken that the capillary remains full of water. The rubber connecting-piece is closed by a strong pinchcock, and a piece of glass rod is slipped into the end of the rubber tube. The pipette is then vigorously shaken, the glass stopcock is closed, the pipette is connected with the poles of an induction coil, and by turning on the current from a fairly strong battery the mixture is exploded.

The glass stopcock is at once opened and the remaining gas is transferred without delay to the burette, and, after three minutes, measured. The result here was 78 c.c.

The total contraction was therefore $99.6 - 78 = 21.6$ c.c.

The gas remaining from the combustion is now passed into the caustic potash pipette, drawn directly back into the burette, and, after three minutes, measured. The reading was 73.2 c.c. Hence by the combustion $78 - 72.2 = 4.8$ c.c. of carbon dioxide was formed.

Although this gave all the data necessary for the calculation of the analysis, the remaining gas was nevertheless passed into the alkaline pyrogallol pipette in order to be sure that an excess of oxygen was present in the combustion, or, in other words, that the gas was completely burned. The measurement gave 70.2 c.c.

Hence there was $73.2 - 70.2 = 3$ c.c. of oxygen in excess.

In the combustion of the marsh-gas its own volume of carbon dioxide is formed, as may be seen from the equation representing the reaction:

$$\underset{1\text{ vol.}}{CH_4} + \underset{2\text{ vol.}}{2O_2} = \underset{1\text{ vol.}}{CO_2} + 2H_2O.$$

Hence in the 13.2 c.c. of the gas residue taken for the explosion there were 4.8 c.c. of marsh-gas.

The marsh-gas in the total gas residue of 82 c.c. is found by the proportion:

$$13.2 : 82 = 4.8 : x,$$
$$x = 29.8 \text{ per cent. marsh-gas.}$$

Since marsh-gas in burning unites with twice its volume of oxygen, the contraction which has resulted from the combustion of the hydrogen is found by subtracting twice the volume of the carbon dioxide found from the total contraction. $21.6 - (2 \times 4.8) = 12$ c.c. contraction due to the burning of hydrogen.

One volume of hydrogen unites, in burning, with one-half its volume of oxygen; hence the volume of the hydrogen is found by multiplying 12 by $\frac{2}{3}$. Thus the 13.2 c.c. of the gas residue taken for the explosion contained 8 c.c. of hydrogen. The total amount of hydrogen is given by the proportion:

$$13.2 : 82 = 8 : x,$$
$$x = 49.6 \text{ per cent. hydrogen.}$$

The nitrogen is found by subtracting the sum of all the other constituents from 100. This gives 2.6 per cent.

Hence the illuminating gas contained:

4.1	per cent.	carbon dioxide.
4.3	"	heavy hydrocarbons.
0.0	"	oxygen.
9.6	"	carbon monoxide.
29.8	"	methane.
49.6	"	hydrogen.
2.6	"	nitrogen.
100.0		

Instead of determining the hydrogen indirectly, as just described, it may be absorbed by means of palladium

sponge. The arrangement of the apparatus for carrying out the reaction is shown in Fig. 193.

The gas burette *A* and the gas pipette *B* are joined together by means of the capillary tubes *E* and the tube *H*. This tube *H* is of about 4 mm. internal diameter and 20 ctm. total length, and it contains 4 grammes of palladium sponge.

The gas pipette upon the stand *G* is filled with water, and its only use is to render it possible to repeatedly pass the gas through the palladium tube.

To determine the amount of hydrogen present in a mixture of hydrogen, nitrogen, and marsh-gas, from which, so far as possible, the absorbable constituents have already been removed, measure the gas in the burette, join it in the manner described to the pipette *B*, which is filled with water nearly to *i*, place the tube *H* in a large beaker containing warm water of from 90° to 100° C., and, after opening the pinchcock *d*, drive the gas three times back and forth through the palladium by raising and lowering the tube *a*. Then replace the hot water with water of the temperature of the room, and lead the gas residue twice back and forth through the tube in order to completely cool the gas. It is in this manner possible to absorb with certainty every particle of hydrogen. Upon drawing the gas so far back into the measuring tube that the water in the pipette again stands near *i*, the difference between the two measurements made before and after the absorption corresponds to the hydrogen plus the amount of oxygen in the air enclosed in the U-tube when the apparatus was put together. This air volume, and therewith its oxygen contents, may be determined with sufficient exactness once for all by closing, with a piece of rubber tubing and a glass rod, one side of the tube filled with palladium, cooling the tube to about 9° C. by placing it in cool water, and then, after connecting it by a capillary with a gas burette completely filled with water, warming it to 100° C. by placing it in boiling water. The expansion of the enclosed air volume corresponds to a difference of temperature of 91° C., *i.e.*, to a third of the enclosed volume of gas.

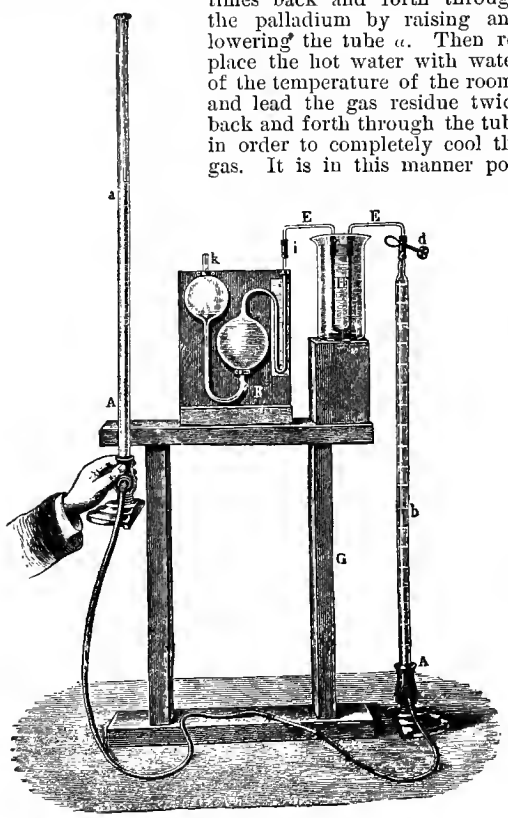

Fig. 193.

The palladium is regenerated after the reaction by first leading air over it, whereby it becomes quite hot; removing any drops of moisture which may collect, so that the palladium may easily be shaken out of the tube in the form of a dry powder; and then superficially oxidizing the metal by heating it on the lid of a platinum crucible.

The residue of nitrogen and marsh-gas which remains after the absorption of the hydrogen is burnt by explosion in the manner described.

The Analysis of Air.—The atmosphere of the earth consists chiefly of nitrogen, oxygen, a small amount of carbon dioxide, and varying quantities of water vapor. In addition to these constant constituents we may expect to find, at times, the various gaseous products of the many chemical processes on the earth, such as ammonia, hydrocarbons, sulphur dioxide and sulphur trioxide. The presence of solid substances, floating in the air in finely divided form, has also been detected. A small amount of the oxygen exists in the form of ozone, the quantity of this gas varying with the weather, time of year, and locality. In an analysis of air, aqueous vapor, carbon dioxide, and oxygen are usually determined. No direct method for determining nitrogen being known, its percentage amount is ascertained by subtracting the sum of the other constituents from 100. In addition to the quantitative determination of the foregoing, qualitative tests to show the presence or absence of carbon monoxide and ozone are often desired. For sanitary purposes the determination of carbon dioxide and water are those most frequently called for.

The Determination of Aqueous Vapor in the Atmosphere.—The water can be determined with great exactness by leading a measured or weighed volume of air through tubes filled with calcium chloride or phosphorus pentoxide, and ascertaining their increase in weight. It hardly need be mentioned that the calcium chloride must first be treated with carbon dioxide, so that it may contain no basic salt which, by taking up carbon dioxide, could change in weight. The common phosphorus pentoxide is never pure, but always contains traces of phosphorus and phosphorous acid. For this reason a current of dry air should be led for some time through the absorption apparatus before it is used.

For most purposes the hair hygrometer and the psychrometer give sufficiently accurate results.

A very fine form of the hair hygrometer, devised by Saussure, is made by Hermann Pfister, in Berne.

The construction of the instrument is based upon the property possessed by hair from which the oil has been removed, of lengthening or shortening according to the amount of moisture in the air. By alternately moistening and drying the hair thoroughly for a number of times, it is given, according to Pfister, the property of quite regular expansion.

Figure 194 shows the arrangement. A hair, prepared as above mentioned, is fastened to a suitable frame. The hair passes aronnd a little wheel below, and the changes in length cause the pointer to move and give the relative moisture directly on the scale.

August's psychrometer is based on the fact that water exposed to the air evaporates the more rapidly, and thereby extracts more heat from its surroundings, the farther the air is removed from the condition of saturation. From the lowering of the temperature $(t - t^1)$ of a thermometer which has been moistened in a suitable manner, the tension e of the water vapor in the air is calculated from the formula—

$$e = e^1 - k\,(t - t^1)\,b,$$

in which e^1 is the tension corresponding to the temperature t^1, b the barometric pressure in millimetres, and k an empirical factor which has, according to the researches of Regnault, the following values:

In small closed rooms	0.00128
" large closed rooms	0.00100
" halls with open windows	0.00077
" courts	0.00074
" open air (no wind)	0.00090

The Determination of Carbon Dioxide in the Atmosphere.—The most varied experience has shown that through the process of breathing the air acquires properties which cause it to act deleteriously upon health when the products of breathing exceed a certain limit. Brown-Séquard and d'Arsonval[8] have shown that air expired by animals has a poisonous action upon other animals, and that this poisonous property is not due to the carbon dioxide present. In fact, they themselves breathed air containing twenty per cent. of carbon dioxide, but otherwise pure, without experiencing any serious inconvenience or lasting effect. Rabbits breathing air which had already been breathed by other rabbits died in from two to six days. The expired air from the first rabbits was

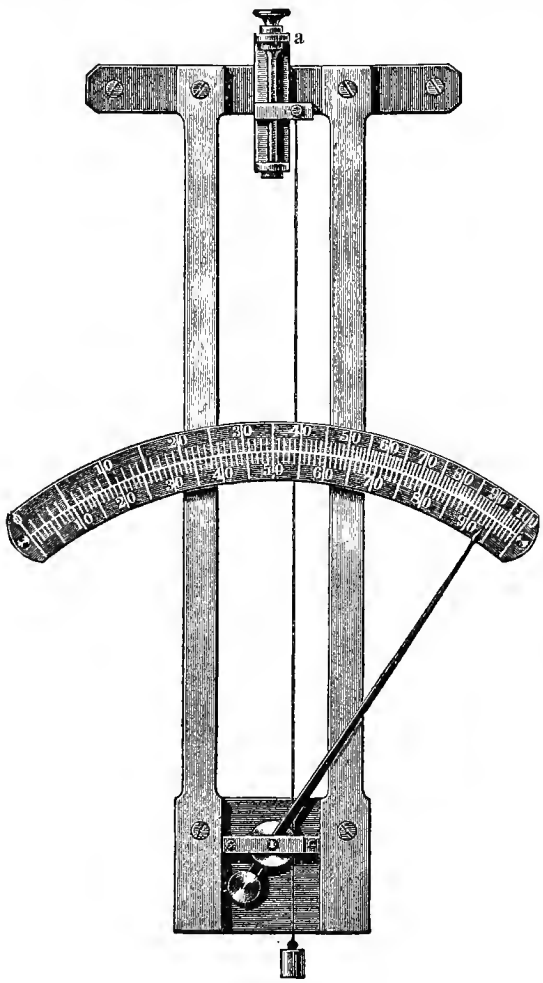

FIG. 194.

then passed through concentrated sulphuric acid, before being breathed by the other rabbits. This sulphuric acid destroyed the poisonous matter coming from the lungs, but allowed the carbon dioxide to pass. The air thus deprived of the pulmonary poison, but charged with the carbon dioxide as before, had no poisonous action upon the animals breathing it.

In examining the air of rooms, halls, or theatres, it is of the utmost importance that we be able to ascertain to what extent the air has been vitiated by the exhalations of the people present. Unfortunately we are not able by ordinary means to determine the amount present of the organic impurities given off by the lungs, but inasmuch as these injurious substances are exhaled simultaneously with carbon dioxide their amount can be indirectly ascertained by determining the amount of carbon dioxide in the room, and for this reason we make use of Pettenkofer's suggestion and judge of the purity of the air by the per cent. of carbon dioxide present.

In the open air the per cent. of carbon dioxide is quite constant, the average amount being 0.04 per cent. by volume, or four parts in ten thousand. In rooms where the air impresses the new-comer as being "good," the carbon dioxide usually varies from 0.055 per cent. to 0.087 per cent. Pettenkofer states that as soon as the carbon dioxide reaches 0.1 per cent., an odor becomes noticeable, and he places this amount as the limit of admissible carbon dioxide resulting from breathing. Yet the air in crowded school-rooms and in well-filled halls and theatres will be found in most cases to contain carbon dioxide far in excess of 0.1 per cent., the amount often rising to from 0.25 to 0.4 per cent. To ascertain the rate of increase of carbon dioxide in smaller rooms, the writer recently analyzed the air of a room about 40 × 20 ft. and 11 ft. high, occupied by thirty-eight adults. At the beginning of the session the air contained 0.058 per cent. of carbon dioxide, and

at the end of		28	minutes,	0.070	per cent.	CO_2,
"	"	39	"	0.101	"	"
"	"	58	"	0.128	"	"
"	"	83	"	0.148	"	"
"	"	103	"	0.240	"	"

One of the best methods for quantitatively determining the carbon dioxide in the atmosphere is that first used by Saussure,[18] and modified by Pettenkofer.[19] It consists in absorbing the carbon dioxide of a measured volume of air with a barium hydroxide solution of known strength, and then determining, by titration with oxalic acid, the amount of barium hydroxide still unacted upon. This method has been used by many investigators, and has been modified in minor details. A very practical form is that devised by W. Hesse, which is as follows:[6]

The necessary apparatus may be divided into a stationary and a portable portion.

A. The reserve apparatus in the laboratory comprises the following:

1. A glass balloon, or large bottle, holding several litres, and filled with a concentrated solution of barium hydroxide. One kg. of barium hydroxide and 50 grammes of barium chloride are put into from 4 to 5 kg. of distilled water. As the solution is used it is replaced by water as long as there is material in excess to saturate the water.

2. A bottle containing dilute baryta water. The bottle is provided with a small absorption flask containing pumice-stone saturated with caustic potash, for freeing the entering air from carbon dioxide (Fig. 195). This dilute baryta water is made by adding about 30 c.c. of concentrated barium hydroxide solution to 1 litre of water, or directly by dissolving 1.7 gramme of a mixture of barium hydroxide and barium chloride (20 : 1) in 1 litre of distilled water.

3. A solution of oxalic acid containing 5.6325 grammes of crystallized oxalic acid in 1 litre of water. 1 c.c. = 1 c.c. CO_2.

4. A solution of phenol-phthaleïn, 1 part in 250 parts of alcohol.

B. The portable apparatus comprises—

1. Five thick-walled conical Erlenmayer flasks of $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{12}$, and $\frac{1}{16}$ litre capacity, and supplied with well-fitting double-bore rubber stoppers. The point to which the rubber stopper reaches is marked on the first four flasks, and their capacity up to this mark is written on the outside of each flask with a diamond. The openings of the stoppers of these four flasks are closed with pieces of glass rod from 3 to 5 ctm. long. These rods are well rounded at the lower ends, the upper ends being widened like a button.

2. A thick-walled 10 c.c. pipette.

3. A glass stopcock burette holding from 10 to 15 c.c., graduated in tenths, and having a tip 7 to 10 ctm. long.

4. A 300 c.c. flask provided with a small guard bottle, as in *A*, 2, and filled with dilute baryta water. This is

filled in the laboratory by connecting it with the large reserve bottle containing dilute baryta water, and driving the solution over through the siphon. Before beginning the experiment a few drops of a solution of rosolic acid are added to the barium hydroxide solution. The fainter the color the sharper is the reaction, but the color must not be so faint as to be indistinct. The proper coloration will last for about three days ; it is then so indistinct that a few drops of rosolic acid must again be added.

5. A 250 c.c. bottle filled with dilute oxalic acid. This is prepared by bringing 25 c.c. of the standardized oxalic acid into the 250 c.c. flask, and then filling the flask to the mark with water.

6. A thermometer.

7. A barometer (a small aneroid).

The amounts of solutions here given for the portable apparatus are sufficient for thirty separate determinations ; in other words, at least ten analyses, including a control determination each time and the standardizing of the solution, can be made with the above quantities.

Each determination of carbon dioxide by Hesse's method is a double one, the two determinations being made with volumes of air of different size. Accordingly, flasks of $\frac{1}{2}$ and $\frac{1}{4}$, or $\frac{1}{2}$ and $\frac{1}{8}$, or $\frac{1}{2}$ and $\frac{1}{16}$ litre capacity are used for taking the samples of air, the sizes of the flasks chosen depending upon whether a smaller or a larger amount of carbon dioxide in the air is to be expected. The samples are taken by completely filling the flasks at the place where the air is to be examined with water which has the temperature of the place, and then emptying the flasks and rinsing them

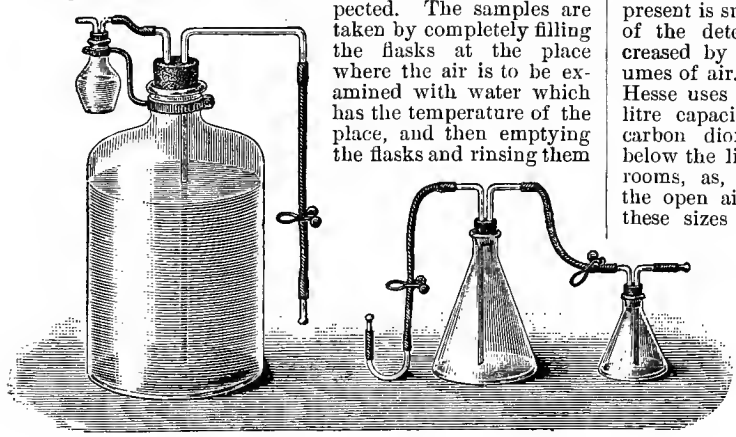

Fig. 195.

with distilled water. In this operation care must be taken that the flask is not warmed by the hand, and that no air exhaled by the operator enters the flask.

To absorb the carbon dioxide, the 10 c.c. pipette is put through one of the openings of a stopper fitting the flask, its end is inserted in the rubber tube of the supply flask, and the pipette is rinsed with a little barium hydroxide solution drawn up into it. The pipette is now filled to the zero mark by suction, and the stopper through which it passes is inserted in the neck of the flask containing the sample of air. The barium hydroxide is now run into the flask, the second opening of the stopper being obstructed with the finger or a glass rod to such an extent that the displaced air can just escape. The glass rod is then pushed into place, and the pipette is freed from the few drops of solution adhering to it by closing it at the top and warming it with the hand. The pipette is then drawn out of the stopper, and the second opening is closed with a glass rod. The same proceeding is repeated with a second flask of different capacity. The two flasks are allowed to stand for some time with occasional shaking, and in the meantime the strength of the baryta water is determined.

The strength of the baryta water is determined by putting into the small flask of $\frac{1}{16}$ litre capacity nearly as much standardized oxalic acid solution as will be required in the titration, and then running in 10 c.c. of the solution of barium hydroxide. The solution is then neutralized by slowly running in more oxalic acid, and the total oxalic acid necessary is thus determined. By proceeding in this manner a very exact standardizing of the solution is possible, even in an atmosphere containing much carbon dioxide, because the solution is never strongly alkaline enough to absorb appreciable amounts of carbon dioxide from the air.

The baryta water which has been shaken with the air is titrated without previously removing the barium carbonate. The titration is made as follows :

Remove the glass rod from one of the openings in the stopper, and immediately insert the tip of the burette which has already been filled with oxalic acid solution. The tip of the burette should reach as far as possible into the flask (Fig. 196). Open the stopcock of the burette and allow the oxalic acid to enter rapidly at first, but at the last only drop by drop. If the increased pressure resulting inside the flask checks the flow of liquid from the burette, this pressure is removed by lifting the glass stopper for a moment. When the solution is neutral, *i.e.*, when it is completely decolored, the height of the solution in the burette is noted, and the contents of the second flask is titrated in the same manner.

It is clear that when the amount of carbon dioxide present is small, the accuracy of the determination is increased by using larger volumes of air. For this reason Hesse uses a flask of $\frac{1}{2}$ or 1 litre capacity whenever the carbon dioxide is probably below the limit for dwelling-rooms, as, for example, in the open air. He also uses these sizes when great accuracy is desired. Of course sufficient barium hydroxide solution must be taken to insure its being present in excess up to the end of the operation. The small amount of carbon dioxide which the baryta water takes up from the air that it displaces when running into the flask may be disregarded.

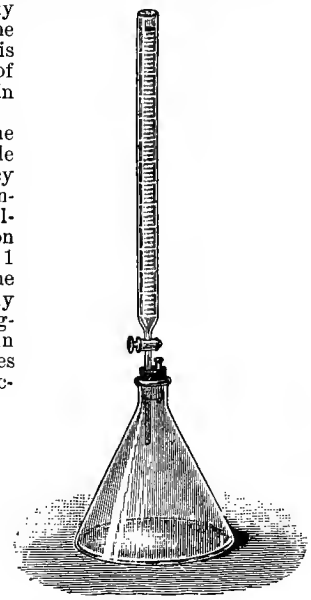

Fig. 196.

In using this method for determining the carbon dioxide present in the soil or in walls Hesse employs the apparatus shown in Fig. 197. The air in the soil is drawn through the flask by means of a rubber pump ; the glass tubes are then removed, and the openings in the stopper are closed with glass rods. The titration is made as before described, but more concentrated reagents are required. In examining the air of graves, Hesse used a solution of barium hydroxide ten times as strong as that previously given (10 c.c. = about 10 c.c. oxalic acid solution A3 = 10 c.c. CO_2).

In calculating the analysis the volume of air taken is reduced to normal pressure and temperature, so that correct comparisons may be made. This calculation takes considerable time, and to Hesse belongs the merit of having compiled a table [21] giving the figures by which the amounts of carbon dioxide found in the uncorrected gas volume are to be multiplied. The table contains for each degree of temperature the multiplier for any barometric pressure.

Example—

$$V = 223 \text{ c.c.}, t = 19^{\circ}, b = 739 \text{ mm.} ;$$

the titration of the baryta water gave 10 c.c. baryta water = 11.5 c.c. oxalic acid, and in the experiment 6.2 c.c. oxalic acid was used. Hence the amount of carbon dioxide which had already united with the barium hydroxide was equivalent to 11.5 − 6.2 = 5.3 c.c. oxalic

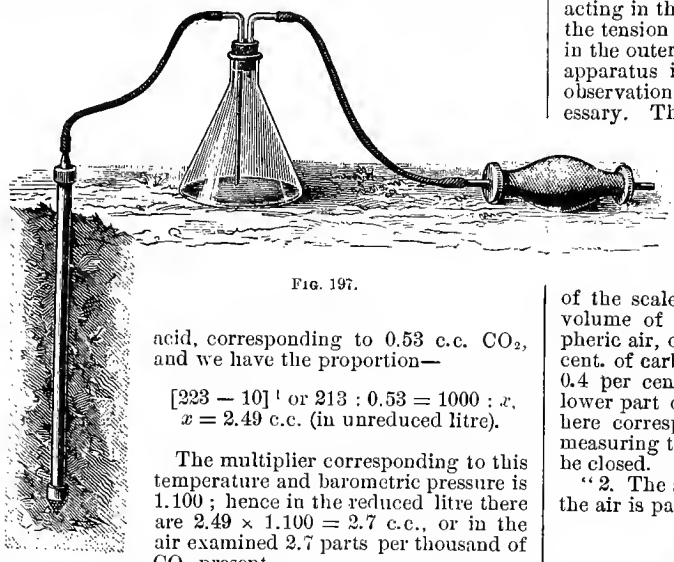

Fig. 197.

acid, corresponding to 0.53 c.c. CO_2, and we have the proportion—

$$[223 - 10]^{1} \text{ or } 213 : 0.53 = 1000 : x,$$
$$x = 2.49 \text{ c.c. (in unreduced litre).}$$

The multiplier corresponding to this temperature and barometric pressure is 1.100; hence in the reduced litre there are 2.49 × 1.100 = 2.7 c.c., or in the air examined 2.7 parts per thousand of CO_2 present.

The whole operation, including the control determination and the calculation, may be completed in from a quarter to half an hour.

Pettersson and Palmqvist have described [10] an apparatus for determining carbon dioxide in air, with which very accurate results can be obtained in a few minutes. Their description of the apparatus is, in part, as follows:

"Fig. 198 shows the apparatus which we used, and which is easily portable. The apparatus can be covered by a wooden box which fits over it, and to which a metal handle is strongly fastened (this cover is not shown in the figure). When the apparatus has been brought to the place where the air is to be examined, the glass jacket is filled with water, the outside air is drawn in through the tube *e*, and by a few simple manipulations, which take only a few minutes, the carbon dioxide is determined with an accuracy of about 0.01 per cent. The dimensions of the apparatus are as small as possible. For example, the pipette *A* into which the air to be analyzed is drawn holds only about 18 c.c. With larger volumes of air it would be easy to attain greater accuracy.

"The carbon dioxide is absorbed in the Orsat potash-tube *B*, and the air is measured, before and after the absorption, in the pipette *A* and its graduated tube. The measuring pipette can be filled with mercury or air, or emptied of the same, by raising or lowering the mercury reservoir *E*, which is joined to the lower end of the graduated tube of *A* by means of a rubber tube wrapped with copper wire. There must always be a drop of water on the surface of the mercury; the air standing over the mercury is thus kept saturated with moisture. In reading the volumes the meniscus of the mercury is each time so adjusted that the pressure in *A* is exactly the same as the pressure of the air in the compensation cylinder *C*.

"A differential manometer containing a drop of a colored liquid (petroleum, in which azo-benzol is dissolved), and connected by capillary glass tubes on the one side with *A* and on the other with *C*, serves as the indicator in these operations. By moving the reservoir *E* and then—having closed the stopcock *d*—suitably turning the screw *e*, the level of the mercury in *A* is so adjusted that the drop of liquid in the manometer stands at zero. It is obvious that in this manner it is always possible to bring back the air in *A* to the same pressure as that prevailing in the compensator *C*. Since the air in both the compensator and pipette is, from the beginning of the experiment, separated from the external atmosphere by closing the stopcocks *f*, *g*, and *c*, any variations in the external atmosphere have no effect. This is also true of changes in temperature; these eliminate themselves by acting in the same manner and to the same extent upon the tension of the air in *A* and *C*, provided that the water in the outer vessel which surrounds the main parts of the apparatus is sufficiently stirred. For these reasons no observation of temperature or barometric pressure is necessary. The changes in volume read off on the scale give directly the amount of carbon dioxide in hundredths of per cent. by volume.

"Each analysis consists of three operations.

"1. The air is drawn in from the outside and is measured, the level of the mercury in the graduated tube being brought to the zero mark. The upper and narrower part of the scale, where each division denotes $\frac{1}{10000}$ of the volume of the pipette, is used in analyses of atmospheric air, or the ordinary air of rooms, where the per cent. of carbon dioxide is at the most not higher than 0.4 per cent. In the analysis of very impure air the lower part of the graduated tube is used, each division here corresponding to $\frac{1}{1000}$ of the whole volume. In measuring the volume the stopcocks *f*, *g*, *b*, *c*, and *d* must be closed.

"2. The stopcocks *d* and *b* are opened, *a* is closed, and the air is passed from *A* to *B*. After one or two minutes

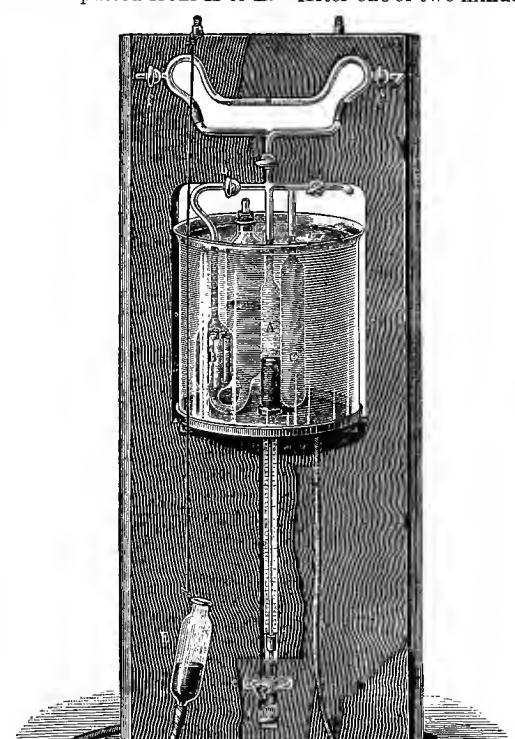

Fig. 198.

the carbon dioxide is absorbed and the air may be brought back into *A*, *b* is then closed, and *a* is opened.

"3. The mercury level in *A* is so adjusted that the index again takes its normal position. The decrease in volume is then read off on the scale."

The Determination of Oxygen in the Atmosphere.—The

great significance which the oxygen in the atmosphere has for all living beings has made this gas the subject of frequent investigations. The amount in a sample of air can be determined with considerable accuracy with the Hempel technical apparatus already described, the oxygen being absorbed in the Hempel pipette filled with alkaline pyrogallol. If, however, great accuracy is desired, methods which admit of more delicate measurement of the gas volumes before and after absorption must be used. The best agreeing results upon the amount of oxygen in the atmosphere seem to have been obtained by Hempel with his apparatus for exact gas analysis (Fig. 186). He collected the samples of air in glass tubes which had previously been exhausted of air, as already described. The oxygen was absorbed with alkaline pyrogallol. Four analyses of the same sample, by one of Hempel's assistants, gave 20.936, 20.938, 20.938, and 20.938 per cent. oxygen.

The Detection of Carbon Monoxide in the Air of Rooms.—The extremely poisonous character of this gas and the ever-present possibility of its production by defective heating apparatus make its sure and easy detection a matter of great importance. If the poisonous effects of carbon monoxide showed themselves only when comparatively large amounts of the gas were present, its detection and the determination of its amount could easily be effected in the customary absorption analysis. Inasmuch, however, as decided symptoms of poisoning are observed when less than $\frac{1}{10}$ of one per cent. of carbon monoxide is present, and as death would probably result from breathing air containing only one per cent. of the gas (a mouse breathing air containing 2.9 per cent. carbon monoxide died with convulsions in from one to two minutes) it is clear that quite delicate tests for the presence of the gas are necessary. The change produced in the absorption spectrum of blood, upon its taking up carbon monoxide, was first utilized by H. W. Vogel,[11] for the detection of small amounts of the gas in the air of a room.

Blood which has been highly diluted with water shows in a layer two centimetres thick (a large test-tube) the absorption spectrum plotted in 1, Fig. 199, and sketched in 2. If this blood be then shaken with carbon monoxide, the bands of the oxyhæmoglobin are replaced by those of carbon monoxide hæmoglobin, 3, the latter lying slightly nearer the violet end of the spectrum. This displacement of the bands, though but slight, is yet sufficient to admit of its being sharply measured, and, in the hands of a practised spectroscopist, is sufficient evidence of the presence of carbon monoxide in the blood. The test is, however, rendered much more delicate by taking advantage of the fact that certain reducing agents, when added to the blood, change the spectrum of oxyhæmoglobin to a broad and weakly defined band, 4, but produce no variation in the spectrum of the carbon monoxide hæmoglobin. In applying these

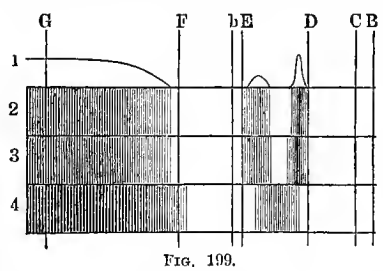

Fig. 199.

characteristics of the blood spectrum to the detection of carbon monoxide in the air of rooms, Vogel filled a 100 c.c. bottle with water, emptied the bottle in the room containing the gas, and then poured into the bottle two or three centimetres of blood highly diluted with water and showing only a faint red color, yet still giving the oxyhæmoglobin bands in a column as thick as a test-tube. The blood is then shaken in the bottle for some minutes. Upon pouring the blood into a test-tube and observing its spectrum through the spectroscope two absorption bands are of course visible, either those of the oxyhæmoglobin or of the carbon monoxide hæmoglobin, or all together. Upon now adding a few drops of strong and freshly prepared ammonium sulphide to the blood, the spectrum, if no CO was present in the air of the room, will change in a few moments to that shown in 4. But

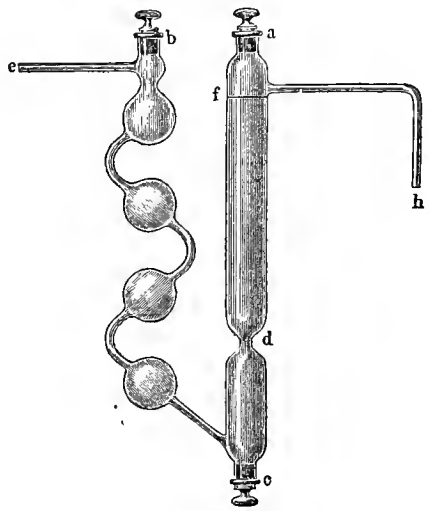

Fig. 200.

if the two absorption bands shown in 3 are still seen, the presence of carbon monoxide in the air under investigation is definitely proved.

Vogel states that amounts down to 0.25 per cent., or 2.5 parts in 1,000, can be clearly detected, but that the delicacy is not increased by using great volumes of air.

Later, Hempel [12] increased the delicacy of the test by using live mice instead of the dilute blood solution. A mouse was made to breathe for some time the air in question, and was then killed and its blood examined spectroscopically, as above. By this means Hempel was able to detect as small an amount as 0.03 per cent. of carbon monoxide.

In 1880 C. H. Wolff described [13] a very effective absorption apparatus adapted to the use of small amounts of blood. As his method is quite as delicate as Hempel's, and does not call for the presence of the difficultly obtained and elusive monse, a description of it is here given.

The apparatus used by Wolff for absorbing the carbon monoxide is shown in Fig. 200.

The tubes are closed at *a*, *b*, and *c* with carefully ground stoppers. In filling the apparatus a little wad of glass-wool is inserted into *d* from above, and gently pressed into place, and the remainder of the tube as far as *f* is then filled with moderately fine powdered glass. This powdered glass is about as fine as ordinary gunpowder. It is freed from any fine powder and dust by sifting, and is then digested with hydrochloric acid, and carefully washed and dried.

The glass powder is moistened with water from above; strong suction is then applied at *e* by attaching an aspirator thereto, and the excess of water which is thus drawn off from the powdered glass is removed at *c*. Two cubic centimetres of dilute blood (1 to 40) is then allowed to drop from above, from a pipette, upon the moistened glass, *a* is closed, and by gently blowing into *h* with the mouth a uniform distribution of the blood solution throughout the column of powdered glass down to the glass-wool is effected. The apparatus is ready for the absorption, and it is now connected either at *e* with the aspirator or at *h* with the bottle, depending upon whether the 10 litres of air are to be drawn through or driven through. An or-

dinary bottle containing somewhat more than 10 litres is very well suited to the taking of the sample of the air to be examined. This bottle is supplied with a double-bore rubber stopper, through the openings of which pass two glass tubes bent at right angles above the stopper.

One of these tubes ends just below the stopper, and the other reaches to the bottom of the bottle. Pieces of rubber tubing of sufficient length, and closed by Bunsen screw-pinchcocks, are slipped over the free ends of both tubes. Since the bottle holds more than 10 litres, it is provided near the bottom with a mark, from which point up to the stopper the capacity is exactly 10 litres. To fill the bottle with the air to be examined, it is filled completely with water, and this is then run out through the rubber tube which is connected to the longer glass tube, and which acts as a siphon. When the water has fallen to the 10-litre mark both pinchcocks are closed. To pass the air through the absorption apparatus, the same rubber tube which has acted as a siphon is attached to a bottle filled with water, and standing higher than the first bottle, and the other rubber tube is connected with the absorption apparatus. The current of air, which may be very exactly regulated by means of the screw-pinchcock, must pass through the absorption apparatus very slowly—on an average 1,000 c.c. in twenty to twenty-five minutes. To be able to observe and regulate the passage of the air through the apparatus, 2 to 3 c.c. of water are run in at *b*, after the powdered glass has been moistened with the blood solution. When the experiment is ended this water is let out at *c*. Any burette-holder is suited to holding the absorption apparatus; a Vogel "universal stand" is also well adapted to the purpose. If it be desired to draw the air of the room in question directly through the apparatus—a proceeding which is, however, not to be recommended, because of the possible change in the composition of the air during the long duration of the experiment—the end *h* is joined by a cork to a so-called calcium chloride cylinder containing pieces of pumice-stone moistened with water. The air enters the cylinder from below, becomes saturated with moisture, and then passes into the absorption apparatus. When 10 litres of air have been led through, in one manner or the other, the stopper at *c* is removed to let out the water. A small test-tube, upon which is a mark for 3 cubic centimetres, is then placed under *c*, the stopper at *a* is removed, and pure water is slowly dropped from a pipette upon the powdered glass. The blood solution is thus gradually displaced, and the washing is continued in this manner until the liquid in the test-tube amounts to 3 c.c. The tube is then taken away, several cubic centimetres of water are allowed to flow through the powdered glass, all the stoppers are inserted, *e* is connected with the aspirator, and when the excess of water has thus been removed the apparatus is ready for another experiment.

The same powdered glass may be used for from fifty to sixty determinations without renewal.

The absorption apparatus contained originally 2 c.c. of dilute blood, 1 to 40; hence the 3 c.c. now in the test-tube have a concentration of 1 to 60.

Small rectangular bottles with flat sides, which are 0.5 ctm. and 1 ctm. wide, are very well suited to holding the blood solution for the observations with the spectroscope: these little bottles hold about 1.5 c.c. of solution, and are closed with carefully ground stoppers. One of these bottles is filled with the blood solution used in the experiment, and a second bottle is filled with the original blood solution, also diluted to 1 to 60. One drop of ammonium sulphide is added to the contents of each bottle; the bottles are shaken, and after half an hour the spectra of the two solutions are examined, preferably by lamp-light, with a delicate pocket spectroscope.

Wolff states that when there is 0.03 per cent. carbon monoxide in atmospheric air, both absorption bands are distinctly recognizable. When the air contains less carbon monoxide, about 0.02 per cent., the presence of the gas is shown merely by a somewhat stronger absorption in the absorption spectrum, which now appears at *D* as a broad band, the maximum absorption of the reduced blood solution lying toward *E*.

It is very desirable to possess for these experiments a solution of blood which is clear and which will keep for a long time. Wolff recommends Jäderholm's method of mixing together equal volumes of blood freed from fibrine, and of cold saturated borax solution, and he says that the solution remains clear for months and does not need to be filtered before being used for the spectroscopic examination.

To determine quantitatively the amount of carbon monoxide in the blood, Fodor suggests placing the blood in a small flask provided with a perforated stopper carrying two glass tubes. One of the tubes reaches to the bottom of the flask, and through it is led in a current of air which has been previously freed from carbon monoxide by passing it through a solution of palladious chloride. The air, after leaving the flask through the shorter tube, is passed through a wash-bottle containing a solution of lead acetate, then through a second bottle containing dilute sulphuric acid, and finally through two **U**-tubes containing a palladious chloride solution as free as possible from acid. The flask is now warmed upon the water-bath to 90° C. for from one-fourth to one-half an hour, the current of air being passed through slowly and the flask being frequently shaken. The carbon monoxide is thus driven out of the blood, and passing through the two wash-bottles it enters the palladium solution, from which it precipitates metallic palladium. The precipitated palladium is collected, dissolved in aqua regia, and the amount of palladium determined by titration with a standard solution of potassium iodide. If a solution containing 1.486 gramme of potassium iodide to the litre is employed, then each cubic centimetre corresponds to 0.1 c.c. CO.

The Detection of Ozone in the Atmosphere.—A large number of reagents may be used for the detection of ozone. For the detection of such small amounts of ozone as are present in the atmosphere, so-called ozone papers are employed.

Houzeau [14] has suggested that this be prepared by dipping strips of Swedish filter-paper into a wine-red litmus solution which contains in a cubic centimetre about 0.013 gramme of the extracted constituents dried at 100° C.: the paper is dried and then impregnated to a fourth of its length with a one per cent. solution of neutral and pure potassium iodide free from iodate. The dried paper must be protected from the air, and is on this account kept in tightly closed bottles.

This paper is colored slightly blue by from 0.0002 to 0.0003 mm. of ozone. In air containing $\frac{1}{261000}$ of its weight of ozone the paper turns blue at once. The part of the paper which is colored with the litmus solution, and is not impregnated with the potassium iodide, serves to show the presence in the air of acid or alkaline substances which might influence the reaction. By the action of ozone the potassium iodide is decomposed and potassium hydroxide is formed, which turns the litmus paper blue. Chlorine, nitric acid, and other acid substances do not, of course, turn the paper blue; in this respect it is superior to those which follow.

According to Schönbein,[15] strips of paper are saturated with a dilute starch and potassium iodide solution (1 KI + 10 starch + 200 water), and these strips are exposed to the air. A distinction of ten shades from white to dark blue is made.

Wurster [16] uses tetra-methyl-para-phenylene-diamene, which, upon taking up one atom of oxygen, is quantitatively oxidized to a blue coloring matter, and by further union with six oxygen atoms changes to a colorless substance.

To detect ozone, the paper prepared by one of the foregoing methods is fastened over the end of a glass tube by means of a rubber band, and a measured quantity of gas is drawn through the tube by an aspirator.

Houzeau found that the ozone in the atmosphere reached its maximum in May and June, and was least in the winter months. Böckel [17] states also that there are daily variations, the air usually containing more ozone

in the evening of days from July to September than in the morning, while the reverse is true for the remaining months of the year.

THE GASES OF THE BLOOD.—Various forms of apparatus have been devised[20] for the extraction of the gases from blood. Probably as satisfactory as any is the Pflüger Mercurial Pump, shown on page 201, Vol. VI., of this HANDBOOK. For facilitating the measurement of the blood before pumping out the gases, Geppert[7] has proposed (page 63) a form of apparatus which with some slight modifications might be of considerable value.

As the blood-gases are chiefly oxygen, nitrogen, and carbon dioxide, the analysis of the mixture is easily performed, the method employed depending upon the amount of gas at the operator's disposal, and upon the degree of accuracy desired. *L. M. Dennis.*

GENITO-URINARY SURGERY. Since the publication of the first edition of the REFERENCE HANDBOOK OF THE MEDICAL SCIENCES the advances which have been made in the department of genito-urinary surgery have been mainly in the direction of therapeutics and pathology. But little has been added to our knowledge of the anatomy and physiology of these organs.

Space will not admit of an exhaustive consideration of all the literature which has appeared, the views which have been advanced, or the many new or revived methods of treatment which have been suggested.

It will, however, be the aim of the writer to take up the subjects, as far as practicable, in the order in which they originally appeared, and to give, as briefly as possible, the practical results of our accumulated experience.

BLADDER.

Exstrophy.—In cases of exstrophy of the bladder, Trendelenburg, with a view to narrowing the anterior gap between the pubic bones, has suggested and successfully practised double posterior symphysiotomy.

Inflammation (Cystitis).—Etiology.—Th. Rossing has contributed the results of some elaborate experiments regarding the etiology of cystitis, and concludes that the urine usually contains one of several varieties of pathogenic organisms. These organisms may be pyogenic or non-pyogenic. Of the organisms which he isolated, all, with the exception of the tubercle bacillus were found to be capable of causing a decomposition of the urea. This decomposition would give rise to vesical irritation, and if the organism was of the pyogenic variety a suppurative cystitis would result.

In twenty-three out of thirty healthy individuals examined by this author bacteria were found in the urethra which were capable of producing this decomposition of urea. In this manner he explains the frequently observed fact of the occurrence of cystitis after the most careful employment of surgically clean urethral instruments.

It was also found that the injection of pure cultures of these organisms into the bladder frequently gave rise to no symptoms of irritation when the urine was allowed to pass at regular intervals. If, however, an artificial retention was produced in the animal by ligature of the penis for from six to twelve hours, a decomposition would be occasioned which would give rise to an inflammatory reaction.

Similar results have been obtained by Guyon, Albarran, and others, and these facts seem to explain the remarkable tendency to infection observed in patients suffering from retention due to stricture or obstructive disease of the prostate.

In a paper published by P. Bazy, the statement is made that in nearly every case of cystitis, where there is a genuine purulent inflammation, the origin may be traced to gonorrhœa, tuberculosis, or infection by means of instruments.

Mechanical irritation alone, such as that produced by a foreign body, new growth, or obstructive urethral or prostatic disease, cannot give rise to a suppurative inflammation. There are, however, certain rare cases, where a cystitis appears spontaneously, without the possibility of gonorrhœa, tuberculosis, or direct septic infection being present. These are usually loosely spoken of as due to "cold" or the somewhat mysterious action of rheumatism or gout.

This author made several such cases the object of careful investigation. In one of these he discovered that an alveolar abscess preceded the symptoms of cystitis by several days; in another, a purulent balano-posthitis, and in still another, a suppurative tonsillitis had been present a short time before the occurrence of the hitherto unexplained vesical inflammation.

The author stated, as his belief, that the disease in each of these instances had been produced by direct infection of the bladder by pathogenic organisms passing from the blood through the renal filter into the urine, the origin of which could be traced to the antecedent septic disease.

Diagnosis.—The possibility of confounding the symptoms of cystitis with those of a posterior urethritis was pointed out in the former edition of this work. Since that time much has been written on the subject, and it is now a generally accepted fact that the occurrence of frequent micturition, vesical tenesmus, and pyuria do not necessarily indicate the presence of intra-vesical inflammation. In fact, in the majority of cases, these symptoms simply indicate the presence of a posterior urethritis, for experiments have abundantly demonstrated the fact that the desire to urinate is due, in a great measure, to an irritation of the peripheral nerves located in the prostatic urethra, caused generally by the relaxation of the internal sphincter, and the consequent introduction of the urine into this portion of the canal. The presence, moreover, of any slight irritation, such as the introduction of a foreign body, or the occurrence of an inflammation of the mucous membrane in this region, will give rise to the desire for frequent micturition, and, if more severe, to marked vesical tenesmus. It has also been conclusively shown that pus generated in that portion of the urethra posterior to the compressor urethræ muscle, when present in any considerable amount, invariably flows backward into the bladder.

If, therefore, in a condition of acute posterior urethritis, the urine be passed in two glasses, both specimens will be found to contain free pus, which continually flows backward from the seat of the inflammatory process into the bladder. The first specimen, in addition, will contain the washings of the canal, which will appear as minute, thread-like bodies, to which the name of *Tripperfaden* has been given by the German surgeons, who first discovered them and demonstrated their importance.

The presence of an anterior urethritis, which might

account for these bodies, may be excluded by a previous irrigation of the anterior portion of the canal.

In cystitis (excepting in those rare instances where the infection is purely a tubercular one) the decomposition of urea gives rise to the presence of a free alkali. This, if allowed to remain in the bladder for a moderate length of time, by its action on the pus, forms a thick, tenacious substance resembling mucin, which collects at the bottom of the bladder, is expelled with the last portion of urine passed, and is pathognomonic of intra-vesical inflammation.

Finger describes three conditions usually spoken of as cystitis: First, posterior urethritis; second, posterior urethritis, with a moderate amount of cystitis in the immediate vicinity of the internal urethral orifice, and third, cystitis without posterior urethritis.

As an easy method of determining which of these conditions are present in a given case, if the patient urinates in three glasses, the following facts will be observed:

Condition.	First specimen.	Second specimen.	Third specimen.
Posterior urethritis.	Reaction generally acid. Large amount of free pus and urethral shreds.	Moderate amount of free pus.	Moderate amount of free pus.
Posterior urethritis, with cystitis about internal urethral orifice.	Reaction faintly acid or neutral. Large amount of free pus; urethral shreds.	Moderate amount of free pus.	Larger amount of pus, and moderate amount of mucoid material.
Cystitis without posterior urethritis.	Reaction alkaline. Moderate amount of free pus.	Moderate amount of free pus.	Large amount of pus and mucoid material, with crystals of triple phosphate.

Treatment.—A few suggestions only can be added to those already mentioned in the first edition of this work.

Internal Treatment.—Many drugs have been employed with a view to rendering the urine antiseptic, and thus preventing or inhibiting the further development of pathogenic organisms in the bladder. Of these, boric acid and salol have been found most useful. To be of value, however, they must be given in large doses, from twenty to thirty grains of the former and from forty to sixty grains of the latter during the twenty-four hours.

Local Treatment.—It is desirable in cases of bladder inflammation, especially if acute, to avoid the use of instruments beyond the compressor urethræ muscle. The old method of bladder irrigation by means of the catheter had the disadvantage of producing often mechanical irritation and septic infection.

Lavaux, of Paris, has shown that the bladder can be successfully irrigated without the use of a catheter by means of hydrostatic pressure furnished by the fountain syringe.

To inject the bladder by this method the patient should be made to recline on his back with the thighs raised to relax the abdominal muscles. The nozzle of the syringe should be placed just within the meatus, the lips being firmly compressed upon it, and the reservoir raised to a height of three or four feet above the patient's body. If the patient will then take three or four deep inspirations, the fluid will usually pass rapidly beyond the compressor urethræ muscle into the bladder. As soon as the bladder becomes distended, a strong desire to urinate will be experienced, and the solution can be expelled in the usual manner. This method has the additional advantage of insuring thorough irrigation of the whole urethral canal, the deeper portion of which is usually involved in cases of cystitis. In the milder cases a saturated solution of boric acid will be found most useful as a bladder-wash. Permanganate of potash, 1 to 10,000; nitrate of silver, 1 to 5,000, and bichloride of mercury, 1 to 30,000 will often be found useful in the more chronic and obstinate conditions.

Injuries of the Bladder.—The tendency among surgeons during the past few years has been toward more radical procedures in cases of ruptured bladder. When the rent in the bladder-wall is known to be extra-peritoneal, measures should be at once taken to insure free drainage, and the wound left to heal by granulation. With this end in view, Cabot, of Boston, advises an immediate laparatomy, with a view to accurately determining the region of greatest infiltration which should guide the surgeon in the selection of his point of incision for drainage.

Since the report by Hofmokl and MacCormac of successful laparotomies and vesical suture in cases of intra-peritoneal rupture of the bladder, there no longer remains any question as to the indications for treatment in this condition. A number of other successful cases have since been reported by European and American surgeons, so that now it is generally conceded that, in the presence of symptoms indicating an intra-peritoneal rupture of the bladder, an exploratory laparotomy should be performed at once, and the wound promptly united. A subsequent perineal section should then be made, to insure adequate bladder drainage.

A number of cases of rupture of the bladder have been collected and reported by Ullmann, the result of injections made preparatory to the operation of supra-pubic cystotomy.

New Growths.—Under this head may be mentioned the *nodular or follicular cystitis*, described by Dr. Samuel Alexander, in a paper read before the American Association of Genito-urinary Surgeons, at Richfield, in June, 1892. This paper was a preliminary report based upon a number of cases of intense cystitis, associated with hæmaturia, upon which the author had operated, in most cases by the supra-pubic method.

In all of these cases similar lesions were found in the bladder. The mucous membrane was intensely congested, and was studded, especially in the region of the trigone, with nodules varying in size from one-eighth to one inch in diameter, usually oval, soft, and limited to the mucous membrane proper. These tumors consisted of lymph nodules and more diffuse collections of lymphatic cells, the former resembling the nodules found in the intestine in certain cases of enteric inflammation. These vesical nodules were surrounded by an exceedingly rich net-work of newly formed capillaries with exceedingly thin walls. The nodules were covered by the upper epithelial layer of the mucous membrane.

This condition has been mentioned by Chiari, Weichelbaum, Hamburger, Toldt, Ziegler, and others, and the post-mortem appearances have been described by Paderowski, who regarded them as tubercular growths. Alexander differs from this view and believes that lymph-nodules exist in the normal urinary tract, and that they may enlarge as the result of intense inflammation, and be often mistaken for tubercles in the bladder. He described the clinical history of these cases and advises supra-pubic cystotomy and thorough drainage.

An extended report and description of this most interesting, and hitherto imperfectly understood, condition is soon to be published.

Stone (*Lithotomy, Litholapaxy, Supra-pubic Cystotomy*).—The statistics published by Sir Henry Thompson, Dittel, and a large number of other operators, embracing thousands of cases of calculus disease, operated upon by all methods, conclusively show the great advantage and low mortality of litholapaxy over all other procedures. Although several modifications have been made in the tubes and evacuating apparatus, practically nothing can be added to the description of the operation of litholapaxy which appeared in the first edition of this work.

The advantages which the supra-pubic method of opening the bladder offers over the perineal incision, for exploration and the removal of foreign bodies and new growths, are now generally recognized by surgeons. Trendelenburg advises for this operation a specially constructed operating-table, which insures an elevation of the patient's pelvis eighteen or twenty inches above the head and shoulders. He also advocates the transverse section of the recti muscles.

Regarding the question of primary vesical suture, Watson, of Boston, reaches the following conclusions from the analysis of one hundred cases: 1. Suture should be employed where the pathological changes in the bladder are slight. 2. Suture should be avoided when the bladder-walls are much thickened, when there is much liability to hemorrhage within the bladder, or when there is a foul cystitis. 3. Short needles and catgut should be used with that form of suture which is most easily introduced.

Tuberculosis.—The treatment of tubercular cystitis by supra-pubic opening, curetting and cauterizing the ulcers, and the subsequent employment of iodoform, has been sufficiently successful in the hands of Guyon, Reverdin, and others to justify the hope that in early cases marked relief may often follow and recovery occasionally result.

Cystoscope.

An instrument designed for the purpose of affording the possibility of an ocular inspection of the interior of the human bladder. This idea was most successfully carried out by Josef Leiter, of Vienna.

The following diagram and description of this instrument appeared in the *Medical Record* for May 5, 1888:

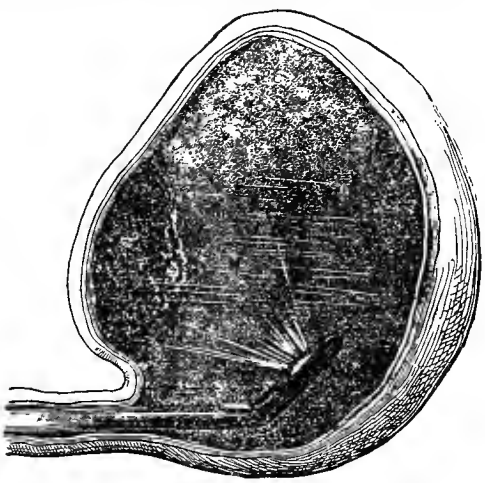

Fig. 201.—The Leiter Cystoscope in Position in the Bladder.

"The Leiter cystoscope (Fig. 202) consists of a metal tube about seven inches in length, of a calibre of 22 F., having at the proximal end a funnel-shaped ocular opening, at the distal end a short beak, similar to that of the catheter coude. A window of rock crystal is set in the end of this beak, behind which a small electric lamp controlled by a switch at the ocular end is placed. A rectangular prism, the hypothenuse plane of which is silvered, is placed in the end of the straight portion of the tube, its superior face being seen just anterior to the angle formed by the beak. The distended bladder is illuminated by the electric lamp, the rays reflected from its walls falling on the prism experience total reflection, an inverted image being formed within the tube. The size of the image thus obtained is greatly increased by means of a telescope introduced into the tube. The image seen through the cystoscope is inverted, but right and left are not transposed."

To properly examine a bladder by means of this instrument, the patient should be placed in the horizontal position on the table or operating-chair. The bladder should be emptied of urine and afterward slightly distended with a solution of boric acid. The cystoscope is then introduced and the current turned on. If the eye of the operator is placed at the eye-piece of the small telescope introduced within the tube of the cystoscope, a limited area of the bladder-wall can be made out. If the fluid remains clear and the light is of sufficient strength, the mucous membrane may be minutely studied, its vessels, folds, and color easily appreciated, and any pathological lesion detected. By changing the position of the instrument, the whole interior of this viscus may be examined.

This instrument has been modified in many ways. When the illuminating and reception windows are placed on the posterior portion of the beak, a better view can often be had of the *basfond* in contracted bladders which do not admit of sufficient distention to permit of free rotation of the beak downward. Care should be taken not to allow, for any length of time, the contact of the illuminated beak with the bladder, as the heat generated by the lamp might cause a superficial destruction of the mucous membrane.

There can be no question of the great diagnostic value and importance of this discovery. By the aid of this instrument, accurate knowledge regarding the presence or absence of tumors, ulcerations, wounds, foreign bodies, and diverticula may be obtained without the necessity of an exploratory operation.

Another and most important use of the cystoscope is to determine from which kidney the blood or pus proceeds in cases of grave pyelitis or renal hemorrhage. By watching the openings of the ureters, the periodic discharge of urine from the kidneys can be observed, and the presence of abnormal substances in the secretion detected.

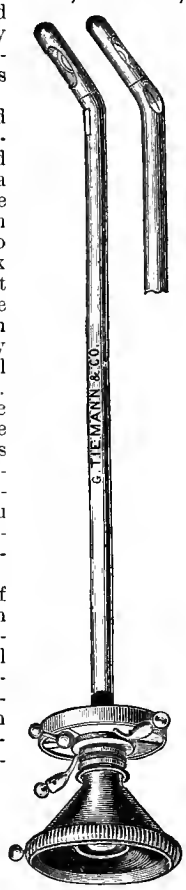

Fig. 202.

Endoscope.

An instrument for the visual inspection of the urethral mucous membrane.

As it would be a useless expenditure of time to describe the old and cumbersome instruments of Desormeaux and Cruise, mention will be made only of the modern instruments of Leiter, Brown, and Otis.

The following description of the Leiter endoscope is quoted from a recent article by W. K. Otis: "Roughly described, this instrument consists of a sheet metal trough, two inches and three-quarters in length by an inch and a half wide, at the proximal end of which a concave mirror, about an inch and a half in diameter, is placed. At the distal end of the trough is the funnel-shaped opening of the urethroscopic tube, the upper edge of which is about half an inch above the upper edge of the mirror. About an inch and a half from the mirror, coming through the bottom of the trough, a small electric lamp is placed, the electrical

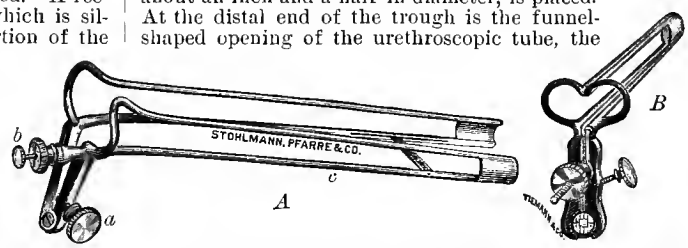

Fig. 203.—*A*, Brown's Wire Urethral Speculum. Open. *c*, The lever for spreading the vesical end, which is governed by the right-angled rod attached to the travelling screw button *b*; *a*, the screw which spreads the base or meatus part of the speculum. *B*, Brown's Wire Urethral Speculum, Closed. Shows the small square aperture in the binding screw for the attachment of the illuminator.

connections to which run through a round handle four inches long by half an inch in diameter, with a somewhat complicated arrangement for controlling the lamp, fitted with binding-posts at its lower end, to which the cords from the battery are fastened. The urethroscopic tubes are attached to the funnel by means of a sliding joint. The rays of the lamp falling upon the mirror are rendered parallel, and enough light thrown down the tube to give very excellent illumination at its distal end, the eye looking directly over the upper edge of the mirror."

The urethral speculum, devised by Dr. F. Tilden Brown, of New York, and seen in the accompanying illustration

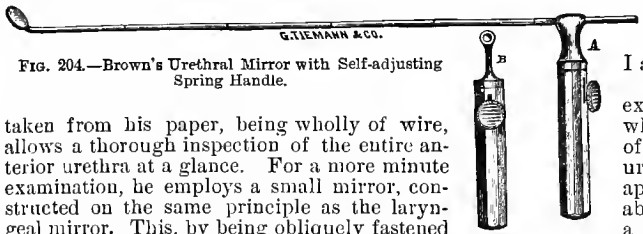

FIG. 204.—Brown's Urethral Mirror with Self-adjusting Spring Handle.

taken from his paper, being wholly of wire, allows a thorough inspection of the entire anterior urethra at a glance. For a more minute examination, he employs a small mirror, constructed on the same principle as the laryngeal mirror. This, by being obliquely fastened to the handle, when passed within the canal, reflects the image of any inequality or pathological condition of the mucous membrane. By means of the urethral digit (Fig. 205), the presence of any submucous deposit or band of stricture can be readily appreciated. The light which Dr. Brown employs is from a strong electric lamp, with lens condenser reflected by means of a head-mirror.

FIG. 205.—Brown's Straight Six-inch Urethral Digit. *C*, The movable probe-tip controlled by U-spring and thumb-screw at handle. Inch marks are indicated along the upper rod.

The Otis perfected urethroscope (Fig. 206) is perhaps the most perfect appliance for urethral illumination. From his article in the *New York Medical Journal* the following description is taken:

"This instrument consists of a metal tube or cylinder, an inch and a quarter in length by half an inch in diameter, closed at one end. A quarter of an inch from the open end of this tube is a plano-convex lens, so arranged that it may be easily removed for cleaning. On the inferior surface, near the closed end of the tube, an elbow is let in, a quarter of an inch in length and half an inch in diameter, through

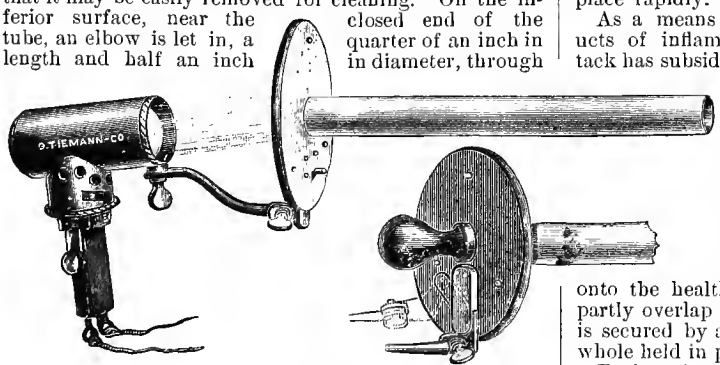

FIG. 206.

which the source of illumination (a small incandescent electric lamp) is introduced, a row of holes being bored at its base to allow of ventilation. The handle of the instrument consists of a piece of hard rubber an inch long by half an inch wide, the electrical connections running through it to the lamp which is placed on top. This handle fits into the elbow by means of a bayonet-joint, bringing the lamp immediately behind the plane side of the lens. A thumb-screw 'switch' in the handle places the lamp under control, so that it may be turned on or off at pleasure.

"The instrument is attached to the urethroscopic tube by means of a stout wire an inch and a half in length, with hinged joints at each end, which swing in opposite directions and are furnished with set-screws, thus allowing the instrument to be put in any position, though when once adjusted it will rarely be necessary to move it. If the ordinary form of tube is used the distal end is provided with a simple ring sliding-joint; but, as I have already said, I greatly favor the use of the tube of Dr. Klotz. I have arranged the instrument for this form of tube.

"When the instrument is in position and the lamp illuminated, a strong beam of light is thrown down the urethroscopic tube and the urethral mucous membrane more easily and clearly observed than with any other form of urethroscope with which I am familiar.

"The advantages of this instrument are: 1. The exclusion of all extraneous light, the presence of which is a most annoying fault in the urethroscope of Leiter. 2. A very much more ready access to the urethral field, both to the eye and for instrumental applications. 3. Increased illumination. 4. By abandoning the funnel and sliding-joint an inch and a half in distance is gained from the source of illumination to the distal end of the urethroscopic tube, increasing the illumination and allowing the eye to be placed just so much nearer the mucous membrane to be examined. 5. Its extreme compactness and lightness, weighing *less than one ounce*, even when constructed of brass. 6. Its great simplicity, which should insure a moderate cost."

EPIDIDYMITIS.

In the *Journal of Cutaneous and Genito-Urinary Diseases*, May, 1888, the writer published the results of some experiments in the treatment of acute epididymitis by means of the Paquelin cautery. The method employed was that first suggested by Halsted, which consists in lightly touching the surface of the skin overlying the affected organ with a white-hot cautery point. This, if successfully performed, requires but a few seconds, and is but moderately painful. A dressing of iodoform or boric acid ointment is then applied, and a suspensory bandage adjusted, so as to relieve any dragging upon the cord. Instant relief of pain often follows this procedure, and absorption of the inflammatory induration takes place rapidly.

As a means of hastening the absorption of the products of inflammation, after the acuteness of the attack has subsided, the *dry poultice* will often be found to be most useful. This dressing was described by the writer in a paper read before the American Association of Genito-Urinary Surgeons, at Washington, in 1891, and consists in a moderately thick layer of cotton-wool applied over the inflamed testicle. This is covered by a layer of rubber protective tissue so fashioned as to completely enclose the inflamed organ, with its edges extending onto the healthy skin of the scrotum in a manner to partly overlap but not enclose the healthy side. This is secured by a snugly applied ganze dressing, and the whole held in place by a suspensory bandage.

By insuring protection, heat, moisture, moderate compression, and suspension, this dressing fulfils all the indications to be met in this condition, and will be found to be a great source of comfort to patients whose occupations necessitate any considerable amount of standing or walking.

HYDROCELE.

Diagnosis.—As an easy method of making an accurate diagnosis in cases of suspected hydrocele, the electric illuminator devised by Dr. William K. Otis may be employed. This instrument consists of small incandescent lamp contained in a cylindrical hard rubber hood (Fig.

207). If the patient be examined in a darkened room, and the open extremity of this instrument firmly held against the posterior portion of the scrotal tumor when the current is turned on, the whole cavity of the tunica vaginalis will be brilliantly illuminated, and the exact location, shape, and size of the testicle can be determined.

Treatment.—The injection into the tunica vaginalis of a small amount (minims 10 to 30) of the liquefied crystals of carbolic acid, which was mentioned in the earlier edition of this work, is the method most generally em-

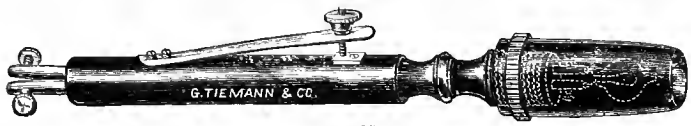

Fig. 207.

ployed at present. The usual manner of employing this agent is the following :

A hypodermic syringe containing the required amount of carbolic acid is inserted through the scrotum into the upper portion of the distended cavity of the hydrocele, and held by an assistant. A large trocar or aspirating needle should then be introduced into the lower and anterior part of the tumor through which the fluid is evacuated. After the complete emptying of the sac, the contents of the hypodermic syringe (the needle of which is still within the cavity of the tunica vaginalis) should be slowly injected, and, after removal of the needle, evenly distributed throughout the entire cavity by gentle massage. The patient should be instructed to remain quietly at home, preferably in the reclining posture, until all reactionary pain has subsided.

With a view to avoiding the double puncture, the writer employs a small trocar and cannula provided with a stopcock and threaded extremity to fit an ordinary hypodermic syringe (Fig. 208). This should be introduced and the fluid withdrawn. The stopcock is then turned to prevent the entrance of air, and the hypoder-

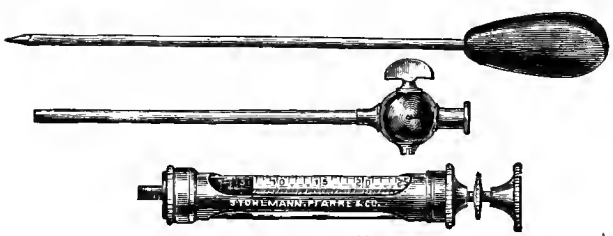

Fig. 208.

mic syringe containing carbolic acid screwed into place ; the stopcock is again opened and the contents of the syringe injected.

Prostate.

Senile Enlargement.—Nothing has been added to our knowledge regarding the causes of this common affection. During the past few years the tendency among progressive surgeons has been toward more radical measures, with a view to the removal of the obstructing portion of the hypertrophied mass. The practice of incising or removing a portion of the bar, which often exists just within the internal urethral orifice, by means of the instruments of Mercier and Gouley, without opening the bladder, has been practically abandoned by most surgeons, owing to the danger attending the operation and the uncertainty of result.

For several years past occasional reports have been published of the successful removal of an hypertrophied third lobe, or obstructing bar at the neck of the bladder, by means of a perineal or supra-pubic opening, with more or less complete restoration of the function of voluntary urination. It was not, however, until the publication by A. F. McGill, of Leeds, and E. L. Keyes, of New York, of their series of cases, that the operation was regarded as a thoroughly justifiable procedure, and the great superiority of the supra-pubic over the perineal method was fully recognized.

Dr. Keyes's method consists in making a supra-pubic opening, and then, by means of the finger-nail, sharp spoon, curved scissors, or rongeur forceps, completely removing all that portion of the hypertrophied gland which surrounds or obstructs the internal urethral orifice, leaving no pocket or pent-up prostatic sinus. The success which has attended the thorough operation advocated by Dr. Keyes would seem to justify the hope that permanent relief may be obtained in, at least, a certain number of these exceedingly annoying and unfortunate cases. For many obvious reasons, the operation in a large number of instances is impracticable, and in these regular catheterization must be employed.

Much has been written upon the great danger of infection attending the first passage of the catheter in cases of chronic retention of urine with atony of the bladder from this cause, and the necessity for unusual care in beginning the " catheter life " of the patient.

Professor Guyon, in the *Annales des Maladies des Organes Genito-urinaires*, for May, 1889, gave the results of a series of experiments upon animals, illustrating the tolerance of the bladder to injected pathogenic organisms when the urine was allowed to pass at regular intervals, and the marked tendency to septic infection which followed even a temporary retention after the introduction of pure cultures of the staphylococcus aureus, streptococcus pyogenes, and the septic bacillus of Clado.

The following method should be employed at the first catheterization of an individual suffering from chronic retention of urine : The patient should remain in bed for at least twenty-four hours after the introduction of the catheter. Previous to its introduction the meatus and glans should be bathed with a solution of bichloride of mercury, 1 to 5,000 ; the urethra, if suppurating, should be injected with a solution of bichloride, 1 to 5,000, or nitrate of silver, 1 to 500 ; if normal, a solution of boric acid, five per cent. will answer. The catheter, if metallic, should be boiled ; if of rubber or gum-elastic, it should be thoroughly washed and treated with seventy per cent. alcohol, followed by a solution of bichloride of mercury, 1 to 1,000. If great distention of the bladder exists, only a portion of the urine should be withdrawn at the first operation, that the circulation may accustom itself to the altered condition of the bladder-walls. Complete emptying of this viscus in extreme cases of distention, should be delayed for eight or ten days. After the removal of the urine a small amount of a saturated solution of boric acid should be introduced and allowed to remain in the bladder. These precautions should be continued until the bladder can be completely emptied without reaction.

Stricture of the Urethra.

The admirable chapter on this disease which appeared in the first edition of this work leaves little to be said on the etiology, pathology, and symptomatology of this condition.

During the past few years the tendency among surgeons has been toward the practical abandonment of divulsion and electrolysis in the treatment of urethral stricture. Regarding the choice of procedures in cases of stricture in the anterior portion of the canal, the same rules will hold as mentioned in the first edition, although it is now the generally accepted belief that internal urethrotomy, when properly performed, offers the only hope of a radical cure in cases of genuine organic stricture. This method has, therefore, become the operation of choice among those surgeons who have to do largely with this class of cases.

The operation advised by Otis is so simple, and, when confined to the anterior portion of the canal, so absolutely devoid of danger, that a brief description of the method of procedure may not be out of place in this connection.

When the stricture occurs at the meatus, or within three-quarters of an inch from the orifice, the operation should consist of an incision made with a straight, blunt-pointed bistoury on the *floor* of the canal; in cases where the stricture occurs at a point deeper than three-quarters of an inch from the external opening, dilating urethrotomy, by means of the Otis dilating urethrotome, should be practised, the cut being made on the *roof* of the urethra. Cocaine is usually employed for anæsthesia. The method of producing cocaine anæsthesia is as follows. By means of an Ultzmann, or long-pointed, syringe, about thirty minims of a four per cent. solution of cocaine is injected into the bulbous portion of the urethra. As the syringe is withdrawn, the lips of the external orifice are gently compressed with the thumb and forefinger. The solution is in this manner retained for ten minutes, which is found to be sufficient to render the entire anterior urethra insensitive, save that portion compressed by the fingers. As this is always the most sensitive part, the hypodermic injection of two or three minims of the solution just below the meatus will render the whole absolutely insensitive to pain. Where this method is fully carried out, the patients rarely complain of pain during the operation. It is necessary to employ ether for anæsthesia only in cases of great nervous irritability, where the sight of blood and the various necessary manœuvres would be followed by disagreeable mental effects, and where the careful exploration of an abnormally sensitive deep urethra or bladder is necessary.

The exact location of the deepest band of stricture is now determined by means of the *bougie à boule*, or urethrometer of Otis, and the dilating urethrotome introduced so that the location of the blade as it emerges from the staff is one-half inch below the stricture. The instrument is then opened until the indicator points to a calibre corresponding to the normal size of the canal, or until the band is stretched to its fullest capacity. The blade is then quickly withdrawn and returned. Each band should be treated in this manner until a full-sized bulb will pass to the bulbo-membranous junction without the slightest obstruction. The hemorrhage is usually slight, and soon ceases by gentle external compression.

Regarding the after-treatment, it has been found that the daily passage of a full-sized sound to the bulbo-membranous junction, during the first four or five days, is by far the most comfortable for the average patient, as the pain attending its passage is always more marked and the hemorrhage more severe after the cut surfaces have been allowed to glue together for two or more days. A sound is usually passed also on the seventh, fourteenth, and twenty-first days after the operation. In cases where an acute urethritis follows the operation, or where the urethra is for any other reason abnormally sensitive, the daily passage of sounds seems often to increase the severity of the symptoms, and in these instances the intervals should be increased to three or four days.

It is rarely advisable to employ cocaine for the passage of sounds during the after-treatment. Where dilating urethrotomy has been practised, the patient should be kept in bed until the danger from hemorrhage has passed, usually from three to five days.

If recontraction of the stricture is to take place, it is usually possible to detect a tendency toward this within fourteen days from the date of the operation. When this is found, further use of the sound should be abandoned, both on account of the severe pain caused by forcing a full-sized sound through an imperfectly divided and recontracting stricture, and also on account of the utter uselessness of attempting to prevent recontraction by means of dilatation. The patient should be allowed to wait until the cut resulting from the first operation has healed, when a second and deeper incision should be made with a view to completely severing the cicatricial band upon which seems to depend the only possibility of a radical cure.

If after three weeks the urethra is healed, and there is no evidence of recontraction of the strictures, the use of the sound may be discontinued, unless the presence of granular patches, an irritable deep urethra, or other similar conditions, calls for its employment. The use of sounds for an indefinite period after an operation, with a view to "keeping the stricture open," is wholly unnecessary. If a stricture is to be cured by urethrotomy, it must be by thorough division, which does away with the necessity of prolonged after-treatment by dilatation.

Regarding the complications which are said to arise so frequently from this operation, the following may be quoted from a paper read by the writer before the New York Academy of Medicine, December 9, 1889, in which an analysis of one hundred and twenty personal cases of internal urethrotomy is reported, and which may serve to call attention to the comparative frequency and treatment of these conditions:

"Among the unfavorable complications which are likely to occur as a result of this operation may be mentioned, first, *severe hemorrhage*. This occurred in six of the one hundred and twenty cases. Of these, three were primary, occurring at or near the time of the operation, and three secondary, occurring after a period varying from one to three weeks. Of the latter, two resulted from a too early indulgence in sexual intercourse; in one it occurred on the ninth day without any ascertainable cause. In but one instance was the hemorrhage alarming, and that was in a case cut on the floor of the urethra.

"In the treatment of hemorrhage it is rarely necessary to institute measures other than rest and gentle pressure applied against the lips of the urethral orifice, as it is only under very exceptional circumstances that the pressure is sufficient to force the blood beyond the compressor urethræ muscle into the bladder. By the use of the perineal crutch properly applied (a procedure first suggested by Dr. F. N. Otis) a more or less constant pressure may be exerted against the deeper portion of the urethra, thereby preventing the backward flow of blood into the bladder, if at any time the action of the muscle seems inadequate. As an effective method of controlling even the most violent hemorrhages from the anterior urethra, Dr. Otis has suggested the introduction of a full-sized endoscopic tube, upon which any amount of pressure may be brought to bear by means of an external bandage. The prolonged application of heat by means of the retrojection of very hot water served in one instance to check a persistent and very annoying hemorrhage.

"It may be stated, I think, with a reasonable degree of certainty, that by careful watchfulness and the employment, when necessary, of these methods, in no case where urethrotomy has been performed need the patient be seriously inconvenienced by loss of blood.

"*Chills and fever* will be mentioned as the second complication likely to follow urethrotomy. This followed the operation in three cases—in one, fever without a chill. In every instance the chill followed the passage of a sound through the deep urethra. The fever without the chill was accompanied by a severe lymphangitis and local sloughing, due to a division of a very narrow meatus during the progress of an acute urethritis.

"*Epididymitis*, as a complication of this operation, occurred in two patients, and in each it followed the passage of a sound through the deep urethra.

"*Infiltration* of urine into the cellular tissue of the penis occurred in one case, where the cut was made on the floor of the urethra. The treatment of this condition consisted in regular catheterization, hot retrojection, and the external application of heat, the object being to prevent its recurrence, to prevent septic infection of the infiltrated tissues, and to promote absorption.

"An *acute urethritis* followed the operation in ten cases. In seven of these the operation was undertaken shortly after an attack of acute gonorrhœa, and was presumably due to the fact that the gonococci had not entirely disappeared from the urethral mucous membrane. In the remaining three cases it could be accounted for only by the use of imperfectly cleaned instruments.

"A slight *ecchymosis* appeared in the skin of the penis in the vicinity of a cut in four of the cases, and is of interest only on account of its relation to a more or less lasting *curvature* of the penis on erection. Of the four cases in which ecchymosis was noted, curvature occurred

in three, or seventy-five per cent. In the remaining one hundred and sixteen patients in which no ecchymosis was noted, curvature occurred but twice, or in about $1\frac{7}{10}$ per cent. of the cases. In but one of the five cases of curvature did the symptoms occasion any marked inconvenience. In this instance the penis, when erect, was bent upon itself at an almost right angle, and was at first extremely painful; this condition continued to a greater or less extent for some seven months. In all five cases, however, the organ eventually became straight and the resulting annoyance was usually slight.

"In three of the five cases of curvature there had been, during the first six or eight days following the operation, an almost entire absence of complete erection of the penis, owing, in two instances, to efforts on the part of the patient to avoid the pain usually attending such an erection. In no instance was there any well-marked induration at the angle of curvature.

"To account for the presence of an ecchymosis of the skin, the escape of blood must have taken place into the loose connective tissue lying between the fasciæ, in closing the cavernous and spongy bodies of the penis. For this to have taken place the cut must have extended through the urethra, the corpus spongiosum, and its fibrous capsule—in other words, the incision was unnecessarily deep. In view of the fact that the large majority of cases of curvature occurred in patients exhibiting an ecchymosis of the skin, it is not irrational to attribute the occurrence of curvature to the same condition, which might easily result in a slight inflammatory thickening of the tissues outside the urethra, or from the presence of an organized clot, either of which would be sufficient to cause a diminution in the elasticity of the tissues which would result in curvature on erection.

"If this view be correct, it is easy to understand how an absence of vigorous erections during the first few days following an operation might favor, while their presence might diminish, the tendency toward formation of inflammatory adhesions.

"In the treatment of this condition use has been made of inunctions of oleate of mercury, of the galvanic current, and of massage. Of these, the latter has proved to be by far the most useful. The method of its application was that suggested by Dr. Frank Hartley, who advises the introduction of a full-sized steel sound; the massage being confined to the neighborhood of the angle of curvature, against the resistance afforded by the sound.

"The prognosis regarding the time necessary to correct this deformity should be extremely guarded; as often, in well-marked cases, a period varying from six months to a year is necessary before the complete disappearance of the symptom.

"Although my records do not furnish an example, *suppression of urine* may occur as a grave complication in cases of urethrotomy. This may arise either from nervous shock, from injury or violence to the deep urethra, or as a result of septic nephritis, and is best avoided by the practice of confining all operative procedure to the anterior urethra, and by the employment of strict antiseptic precautions."

At the close of the paper the following conclusions were drawn, which may fairly be stated as representing the present opinion regarding this operation: "1. That internal urethrotomy as a means of treating stricture of the anterior urethra is a comparatively safe operation, no deaths occurring in my series of cases, and but one case of severe illness, and that directly traceable to my own bad judgment regarding the method of operating. 2. That by the intelligent application of a few well-known measures alarming hemorrhage can in nearly all cases be avoided. 3. That the occurrence of a more or less lasting curvature of the penis after operation is probably due to the extension of the incision beyond the necessary limits, and that a tendency toward this is aggravated by the prevention, by any means, of complete erection of the organ subsequently to the operation. 4. That with the exception of the meatus, the practice of dividing anterior strictures on the floor of the urethra should be condemned as a dangerous procedure. 5. That the passage of instruments through the deep urethra should, if possible, be avoided immediately after the operation. 6. That in a majority of cases, by a thorough and complete division of all stricture bands, a radical cure and complete restoration of the canal to its normal calibre, may be expected. 7. That all attempts to prevent recontraction in imperfectly divided strictures by means of dilatation, are useless."

Resection of the urethra for dense, indurated stricture located in the membranous portion of the canal, has been successfully practised by Heusner, König, and others. Heusner's method consists in first dissecting out the cicatricial tissue. The urethral mucous membrane above and below the stricture is then separated by curved scissors from the submucous connective tissue and the edges united with catgut sutures. The wound is drained and a catheter tied in. By this method it is said that the necessity for constant dilatation after external urethrotomy in these cases is avoided.

Urethritis (Gonorrhœa).

Since the publication of the first edition of this work a very considerable amount of progress has been made in our knowledge of this disease, its causes, its varieties, its general behavior, and its treatment. For several years subsequent to the discovery by Neisser of the gonococcus, the relationship between this micro-organism and the severer forms of urethritis was seriously questioned by the majority of the more conservative members of the profession. This was in part due to the fact that certain views regarding the origin of this affection had long been entertained and taught by many of the most distinguished authorities upon the subject, which were at variance with the conclusions logically following the acceptance of this theory. But the evidence which has been furnished by the pathologists has been so conclusive, and the analogy to other forms of contagious diseases so well marked, that to-day few who have taken the trouble to investigate the subject will undertake to deny the causative relationship which this organism bears to the ordinary contagious form of this affection.

The acceptance of these views has naturally led to a gradual change in nomenclature, classification, prognosis, and treatment. The tendency to abandon the old and etymologically incorrect term *gonorrhœa*, and to adopt the more scientifically correct *urethritis*, has induced the writer to consider the subject under this heading.

Varieties.—*Acute Specific Urethritis*, the so-called true gonorrhœa. A severe, highly contagious inflammation of the urethra, having a distinct period of incubation and characterized by an abundant purulent discharge containing gonococci. This form of disease is invariably caused by contact with the secretions from the diseased organs of a person similarly affected. The duration of this variety, if untreated, is never under four weeks, and usually continues over a period of many months.

Acute Non-specific Urethritis.—A mild contagious urethral inflammation, having a period of incubation characterized by a scanty muco-purulent or purulent discharge, containing no gonococci. This disease has been described by Bockart and others, who attribute the symptoms to infection from micro-organisms contained in the vaginal secretions occurring in leucorrhœa, cancerous disease of the cervix, or during menstruation. The duration of this form of urethritis is seldom over twelve or fourteen days.

Acute Exacerbation of a Chronic Specific Urethritis.—A purulent urethritis, usually mild in character, occurring generally without or with but a brief period of incubation in persons having an uncured urethral inflammation, who, however, may present no outward manifestations of the disease. The secretions usually contain gonococci. Urethritis may also be occasioned by traumatism, by chemical or thermal agents, by rheumatism, gout, and the lesions of tuberculosis, chancroid or syphilis, but these varieties are so infrequent as to render their consideration in this connection superfluous.

Until quite recently the majority of writers upon the subject of venereal disease admit the possibility of an idiopathic urethritis which may be occasioned by the cohabitation of a perfectly healthy man with a perfectly healthy woman, and claim, moreover, that the symptoms, duration, and ultimate results of such a condition differ in no respect from those accompanying the severer and more virulent forms of the disease. Ricord even goes so far as to enumerate, in his now famous "receipt," the conditions of temperament, complexion, the kind and amount of exercise, the diet and the drink which, in his opinion, favor this peculiar and spontaneous evolution of disease.

More evidence, however, must be furnished in support of this theory than that contained in the usual statements that "the man had no discharge" and that the most "careful speculum examination of his companion failed to reveal the slightest trace of disease."

The writer has expended a very considerable amount of time and trouble during the past few years to discover an example of this variety of urethritis, and has investigated with no little care a large number of these supposed cases of "strain," with the result that in no instance was the urethritis to be accounted for in any manner other than by contagion from the gonococci-bearing secretions from some portion of the genito-urinary tract in the female or from the awakening of an uncured urethritis in the male.

In view of our increased knowledge regarding the behavior of gonorrhœal disease in both sexes, no reason exists at present for our accepting this unscientific theory of an idiopathic urethritis.

Diagnosis.—The microscopic examination of the pus derived from a given case of urethritis, with a view to determining the presence or absence of gonococci, furnishes the most reliable data upon which to base an opinion regarding its nature, prognosis, and treatment. If gonococci can be demonstrated in the secretions, we have to do with a case of genuine gonorrhœal or specific urethritis.

The method of making this examination is as follows: A small fraction of a drop of freshly exuded pus is spread into an exceedingly thin layer on a glass slide. This, after drying by passing it rapidly through the flame of an alcohol lamp, is treated with a saturated solution of methyl-blue or gentian violet in aniline water. This is allowed to remain sufficiently long to stain the nuclei of the cells, leaving the surrounding protoplasm clear. The staining fluid should then be thoroughly washed off with distilled water and, after the application of a cover-glass, the specimen examined with a 12th oil immersion. If gonococci be present, they will be seen in clusters in the protoplasm of the pus-cells surrounding the nuclei, as deeply stained, biscuit-shaped diplococci, arranged in pairs or fours. If present in large numbers they may completely fill the cell without exhibiting any special arrangement.

Other varieties of diplococci are said to present appearances so similar to those described above as to render this test alone insufficient to establish a positive diagnosis in a doubtful case. In such instances, use should be made of the test described by M. Gabriel Roux, of Lyons, which is based upon the fact that the gonococcus alone, of all the micro-organisms likely to be found in pus, is not acted upon by Gram's fluid, and consequently loses its color when treated by absolute alcohol.

Roux's test should be made as follows: A specimen of pus should be stained, in the manner above described, with the methyl-blue or gentian-violet, treated with Gram's iodo-iodide solution, mounted, and examined. If diplococci are present in the pus-cells, which wholly disappear after decolorization with absolute alcohol, the organisms are surely gonococci, as all other varieties of cocci retain their stain after this treatment.

Prognosis.—The only point in prognosis which should be added to that contained in the first edition of this work is in regard to the duration of the contagious stage of a specific urethritis. The question is a serious one, especially when considered in its relation to marriage, and should, I believe, be regarded as equal in importance to that of syphilis.

It is not infrequently the experience of physicians to be consulted by young men, a few weeks or months before a contemplated marriage, with a history of one or more attacks of gonorrhœa in former years, and who believe themselves to be well, yet who, upon a careful examination, present the unmistakable signs of a chronic urethritis.

The only evidence of disease remaining in these cases may be, and frequently is, the presence in the urine of small thread-like bodies, to which the name of *Tripperfaden* has been given by the German surgeons who first discovered them and demonstrated their importance. These minute shreds are composed of mucus, pus, and epithelium, and represent the secretions which adhere to any granular patch or area of chronic inflammation remaining on the urethral mucous membrane.

Since the establishment of the relationship of the gonococcus to this disease but one opinion can logically be held by those who accept this theory of gonorrhœal inflammations, and that is, that all secretions containing this micro-organism are capable of transmitting the disease under favorable conditions. In his recently published work upon this subject Ernest Finger emphasizes this point, and states, regarding marriage, that it should be absolutely prohibited in all cases where the existence of a chronic urethritis is evidenced by the presence of the "morning drop" or *Tripperfaden* in the urine, until the following facts have been established: 1, That after from two to four weeks of daily observation the secretions from the urethra are found to be *free from pus and made up wholly of epithelial cells;* 2, that no gonococci can be detected by the microscope, even after a purulent discharge has been established by the employment of irritating injections of corrosive sublimate or nitrate of silver; and, 3, that neither prostatitis nor stricture exists.

Treatment.—The general acceptance of the more modern views regarding the etiology of urethritis has led to the adoption of new therapeutic measures. When we consider that urethritis is a purely local affection, limited during the first few days, at least, to the anterior portion of the urethral mucous membrane, the conclusion is inevitable that the most successful method of treatment will consist in thorough irrigation of the diseased portion of the canal with some agent capable of destroying the germs or, at least, inhibiting their development. Of the remedies employed the most successful have been bichloride of mercury and nitrate of silver.

Bichloride of Mercury.—The first systematic experiments with this agent were made by Dr. William S. Halsted, at the Roosevelt Hospital, in 1884. He found that by irrigating the anterior urethra with a large amount of a very diluted solution of this agent (1 to 40,000) a marked amelioration in the symptoms was at once apparent. His method consisted in allowing from one to two quarts of the solution to pass through the urethra twice daily by means of a fountain syringe and glass nozzle. About the same time bichloride solutions were also employed, though in somewhat more concentrated solutions, by Dr. H. Holbrook Curtis, by means of his hot retrojection apparatus (Fig. 209).

This apparatus consists of a tin pail beneath which is fastened a platform for an alcohol lamp or Bunsen burner. The pail is connected by means of a rubber tube with a No. 14 F. soft-rubber catheter. The patient, seated in front of a slop-jar or pail, introduces the catheter to within one inch of the bulbo-membranous junction. The pail is then elevated, by means of a pulley and cord, to a height of three feet, and the solution allowed to pass rapidly through the urethra from behind forward. The temperature of the fluid is regulated by means of the lamp, and should be gradually raised until it is as hot as the patient can bear.

Some five years ago an opportunity was granted the writer of undertaking a series of experiments at the out-door department of Roosevelt Hospital, with a view to testing the efficacy of the various methods of treating gonorrhœal urethritis. By far the largest number of

cases were treated with bichloride of mercury, for the reason that the results which followed the use of this drug seemed far more satisfactory than those of any of the others. At the end of the first year, by request of the President of the New York Dermatological Society, I reported to that body the results of my work in a paper entitled "Some Observations upon the Modern Treatment of Urethritis." In that communication I limited myself to the consideration of two comparatively new methods of treating this disease, *i.e.*, by continuous irrigation with bichloride of mercury, and by hot retrojection.

From an analysis of about one hundred and fifty cases treated by these methods I felt justified in drawing the following conclusions: 1. That in uncomplicated cases of acute gonorrhœal urethritis, treated by prolonged and

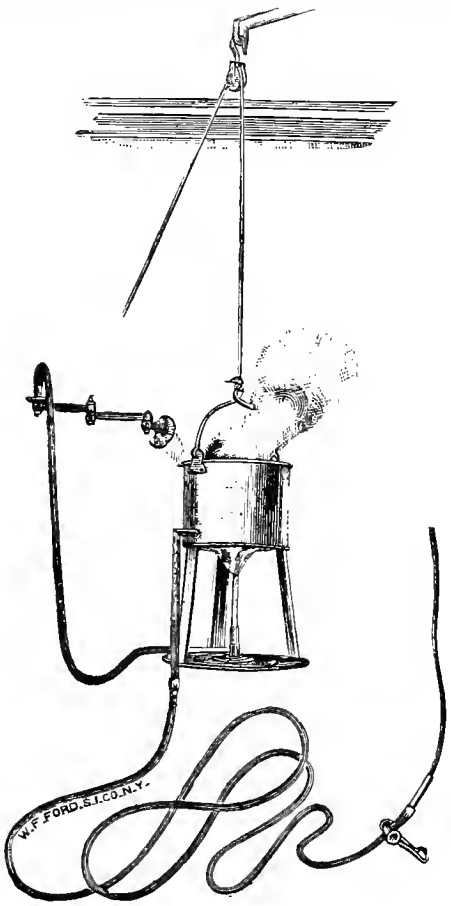

FIG. 209.

frequent irrigation with bichloride of mercury, recovery may be expected within two weeks. That this period may be considerably shortened by the early inauguration of treatment, by absolute rest, and by the avoidance of stimulants; that it may be indefinitely prolonged by irregularity in treatment, by inordinate physical exertion, and by indulgence in alcoholic and venereal excesses. 2. That the retrojection of a hot solution of bichloride possesses all the advantages of the former procedure, and in addition causes a more rapid subsidence of the inflammatory symptoms, a greater feeling of comfort to the patient, and is attended with less annoyance and trouble. 3. That in cases of acute non-specific urethritis the favorable influence of each of these methods is strikingly apparent. 4. That in cases of chronic purulent urethritis no agent produces such rapid and permanent improvement as irrigation, especially when combined with astringents and heat. 5. That the percentage of complications occurring in cases treated by these methods is far below that observed where the ordinary treatment is employed.

At the close of my second year of experiments, at the request of the editor of the *Journal of Cutaneous and Genito-urinary Diseases*, I gave a brief *résumé* of the results in a short contribution to that journal, entitled "Genito-urinary Notes." In this paper one hundred and two additional cases were reported which were treated by the above methods, and at the conclusion of the report the statement was made "that the results obtained were even more satisfactory than at first and fully justify the conclusions with which I closed my first paper."

Regarding the inflammatory complications, I stated that I had encountered but five in over two hundred and fifty cases, or about two per cent., while in three hundred and fifty-two cases treated by other methods, epididymitis alone occurred in sixteen per cent. of the patients.

Cases were occasionally encountered which would not yield to these methods. In all such the urethra was found to be the seat of one or more strictures which rendered its walls rigid and inelastic, thereby preventing the free circulation of fluid within its cavity.

During the past three years I have continued to employ bichloride of mercury in the treatment of this disease at the Vanderbilt Clinic, Presbyterian Hospital, and in private practice, substituting largely the ordinary urethral syringe for the methods by irrigation.

The method adopted in the hospital cases was as follows: As soon as the patient presented himself at the clinic, he was instructed in the proper use of the syringe and given a large amount of a solution of bichloride of mercury, varying in strength from 1 to 16,000 to 1 to 50,000, according to the sensitiveness of his urethra and the stage of the disease. This he was instructed to use twice daily by taking ten injections in the morning and ten at night, holding each one in the urethra one minute, to imitate as nearly as possible the result obtained by irrigation. The patients were usually seen three times a week. As soon as the discharge lost its purulent character the bichloride was suspended and a mild astringent substituted, preferably bismuth suspended in glycerine and water.

Although bichloride cannot be said to be a reliable and abortive agent in the treatment of urethritis, still it undoubtedly exerts a more marked influence in subduing the painful and disagreeable symptoms of this disease than any other remedy at present in use.

Nitrate of Silver.—This agent has long enjoyed the reputation of exerting a most favorable effect in acute and chronic urethral inflammations. Formerly it was largely employed in strong solutions (twenty to forty grains to the ounce) in the early stages, with the idea of aborting the disease.

Quite recently an article appeared in the London *Lancet* describing a method which had been successfully employed by a British surgeon in forty cases of acute urethritis. His method consists in completely removing the pus from the anterior urethra by means of a cotton swab, through an endoscopic tube, and then applying a ten per cent. solution of nitrate of silver over the entire mucous membrane anterior to the bulbo-membranous junction, an extra amount of the solution being used in the fossa navicularis. The patient is then instructed to remain in bed for two days, and employ at intervals a mild astringent injection. The reaction which follows is often quite severe, but of short duration, and no further treatment is required.

Experiments in this country with this method have failed to furnish results as favorable as those reported by this writer.

Guiteras's method of employing this agent consists in administering every second day a single injection of a solution of nitrate of silver, beginning with a strength of one-half to one grain to the ounce of water, and increasing by one grain at each application until the strength of ten grains is reached. Before and after this application the anterior urethra is irrigated with a saturated solution

of boric acid. During the intervals between the injections, which are administered by the surgeon, the patient employs an urethral wash of boric acid, or a mild solution of zinc acetate. This method is at present being tested in a number of clinics, and with no small measure of success.

Posterior Urethritis.

The importance of posterior urethritis as a complication of the acute form of the disease has not until quite recently been fully appreciated. Under ordinary circumstances, in an attack of acute urethritis, the inflammatory process is limited to the pendulous urethra or that portion of the canal anterior to the compressor urethræ muscle. The reason of this is that the membranous urethra, being much less vascular and almost devoid of glands and follicles, offers an effective barrier to the backward progress of the inflammation. When, however, this barrier is passed, and the disease extends to that portion of the canal posterior to the compressor muscle, we have to do with a condition far more grave, not only from the fact that the discomfort to the patient is greatly increased by painful and distressing symptoms, but also from the fact that a much larger extent of the mucous membrane is involved, and the liability of a still further extension to other important organs is rendered probable.

Symptoms.—This complication may occur with practically no subjective symptoms. Generally, however, the patient experiences a heavy feeling in the perineum, accompanied by an increased frequency in urination and pain extending along the course of the urethra at the close of the act. In the severer cases, the calls to urinate may occur every few minutes, and be accompanied by marked dysuria and bladder tenesmus. There is also, generally, marked sexual hyperæsthesia. Not infrequently the last few drops of urine passed will contain blood.

If the urine be examined by means of the two-glass urine test (described under Inflammation of the Bladder) the first portion will contain free pus and urethral shreds, the last free pus, and possibly a certain amount of blood, due to the violent contraction of the prostatic muscle. This condition is often mistaken for acute cystitis. For the differential diagnosis of these conditions the reader is referred to the section on Diseases of the Bladder.

Prognosis.—If the occurrence of this complication is recognized early, before the inflammation has had sufficient time to penetrate the glands and follicles of the prostate, and prompt measures are undertaken for its relief, the duration is often but a few days. If, however, the case is neglected and allowed to become chronic, it presents serious difficulties, and is frequently most rebellious to treatment. The chief importance, however, lies in the fact that it renders the patient far more liable to an extension of the disease to the prostate, seminal vesicles, bladder, and testicles. It is highly probable that none of these complications ever occur without a previous posterior urethritis. The importance, therefore, of an early diagnosis and prompt treatment is patent.

Treatment.—When the diagnosis of an acute posterior urethritis has been established, absolute rest in bed should be insisted upon, and an increased flow of urine brought about by the use of diuretics. The pain and frequency of urination should be controlled by opium or morphine suppositories. The local application of a solution of nitrate of silver by means of the Keyes deep urethral syringe is perhaps the most useful procedure which can be employed in this condition. The strength of the solution should be at first not more than five grains to the ounce of distilled water. Of this, five or ten drops should be deposited in the deep urethra, after the manner described in the earlier edition of this work. Later, the strength should be gradually increased until that of fifteen or twenty grains to the ounce is reached. These applications should be made not oftener than once in three or four days.

The first effect of the treatment is to cause a slight increase in the pain and dysuria. This is later followed by a decided amelioration in all the distressing symptoms. The relief in such cases is often strikingly satisfactory; the most acute and painful seem often to yield most promptly. If the condition becomes subacute or chronic, great benefit often follows irrigation of the posterior urethra and bladder by means of the Ultzmann deep urethral irrigating catheter (described under Chronic Prostatitis in the earlier edition of this work); the solutions found to be most serviceable in this condition being a saturated solution of boric acid, permanganate of potassium (1 to 5,000), and nitrate of silver (from 1 to 2,000 to 1 to 10,000).

Chronic Urethritis.

Practically nothing can be added to the excellent description of chronic urethritis which appeared in the earlier part of this work. In the treatment of this most obstinate condition, however, much has been learned which will be found to be of positive value. These advances have been largely in the line of local treatment.

As perhaps the best method of calling attention to the advances in the therapeutics of chronic urethritis, and of noting the indications for each procedure, the following plan of treatment may be mentioned, which embraces the best of the old methods, together with any new suggestions which have been made during the past few years, and which have been found to be of real value.

When a patient suffering from a chronic urethral discharge presents himself for treatment, the first step is to determine the location of the diseased area from which the secretion arises. This can be accomplished by an ocular inspection of the anterior portion of the canal by means of the endoscope, and by the careful employment of the two-glass urine test.

The next step is to determine the presence or absence of four conditions which are known to prevent or retard the restoration of the mucous membrane to its normal condition of health. These conditions are stricture, the use of alcohol, sexual indulgence, and general ill-health from tuberculosis, syphilis, anæmia, malarial poisoning, etc. If stricture exists it should be removed by urethrotomy or its untoward influence overcome by the use of sounds. The use of alcohol should be prohibited and all sources of sexual excitement removed. The general health, if impaired, should be restored by the use of rational hygienic and medicinal measures. After this has been accomplished local measures must be relied upon to effect a cure.

If the inflammation is limited to the anterior urethra, injections of solutions of the mineral astringents may be employed. Of these, the best are the acetate, sulphate or sulpho-carbolate of zinc, permanganate of potassium, nitrate of silver, or bismuth suspended in glycerine and water. Of all agents used to cause a rapid cessation of a chronic, muco-purulent discharge from the anterior urethra, none can be relied upon to act more happily than injections of the subnitrate of bismuth suspended in glycerine and water, in the proportion of one ounce of bismuth to four ounces of the fluid. This should be well shaken to insure a complete distribution of the bismuth throughout the fluid, and a syringeful slowly injected after each urination. The mixture should be held in the urethra at least sixty seconds, to allow a thorough precipitation of the powder upon the urethral walls.

While the effect of this agent is not always in itself curative, by subduing any co-existing irritation of the canal it not infrequently happens that under its use the chronically inflamed surfaces take on a healthy, reparative action. The use of full-sized sounds to distend the canal once or twice a week, will often be found to be of great value, alone or combined with the local use of astringent agents.

If no improvement follows the careful use of these measures, after a conscientious trial of from ten days to

two weeks, local application should be made upon the granular patches, superficial erosions, or areas of chronic inflammatiou by means of the endoscope and cotton applicator.

Of all the agents employed for topical application nitrate of silver will be found to be the most useful. A strength of two and one-half grains to the ounce should be at first employed, and this gradually increased until a strength of twenty to thirty grains is reached. These applications should be made not oftener than once in every four or five days. It is often advisable to alternate this treatment with that by the passage of sounds.

The duration of the treatment is exceedingly variable. When the disease is of comparatively recent origin, recovery may be expected in two or three weeks. If, however, the process has been going on for months or years, the disease has in all probability penetrated the glands and follicles emptying into the urethra, each of which with its surrounding capillary net-work acts as a miniature incubator for the development of micro-organisms of disease, and exudes at intervals minute drops of germ-laden pus which serve to reinfect the surrounding mucous membrane.

When the disease has involved these glandular structures of the urethra it can be eradicated only by the most persistent measures, and often treatment extending over a period of many months is necessary to effect a cure. If the disease is found to be located in the posterior urethra measures must be employed which insure thorough irrigation of this portion of the canal and the application of astringent or antiseptic agents. This is best accomplished by the use of the deep urethral irrigating catheter and syringe of Ultzmann. The catheter should be introduced as far as it will go, which insures the beak being just beyond the compressor urethræ muscle. A syringeful of the fluid should be rapidly injected and allowed to remain for several minutes in the bladder. This should afterward be passed out by the expulsive efforts of the patient, which insures a double irrigation of the posterior urethra and the therapeutic effect of the substances contained in the injected fluid.

Of the agents employed in this manner may be mentioned carbolic acid, 1 to 100, permanganate of potassium, 1 to 5,000 or 10,000, sulphate of zinc, 1 to 500, and nitrate of silver, 1 to 10,000 to 1 to 2,000. This treatment should be employed every day.

The occasional local use of a stronger solution of nitrate of silver, by means of the Ultzmann or Keyes deep urethral drop-syringe, is often of great value in connection with the plan above described. Five or ten minims of a solution varying in strength from one to twenty grains to the ounce, may be employed once or twice a week.

Dr. Keyes has also successfully employed with this instrument a somewhat larger amount (thirty to forty minims) of a solution of sulphate of copper, thallin, and other astringents.

Sounds are often of the greatest service in the treatment of posterior urethritis. The same rule should govern their employment as in the cases where the disease is confined to the anterior portion of the canal. It not infreqently happens that the introduction of any instrument into the posterior urethra results in marked local inflammation and grave systemic disorders. In these cases the irrigation of the whole urethra and bladder should be accomplished from the meatus by means of the fountain syringe, in the manner described under the treatment of cystitis, the same solutions being employed as with the deep urethral irrigating catheter. These cases are often extremely persistent and annoying, and the treatment should be accompanied by the greatest amount of patience and care, special attention being paid to the removal of all the causes mentioned above as likely to retard the recovery.

Vesiculitis.

An inflammation of the seminal vesicles and their excretory ducts. This complication of urethritis, though an infrequent one, is often most annoying alike to the patient and the physician. The symptoms of the acute stage are throbbing pain in the perineum and rectum, increased by defecation, and a more or less persistent priapism with frequent seminal emissions, accompanied by excessive voluptuous sensation. The fluid ejaculated is brownish in color, and if examined microscopically is found to contain pus, blood, and dead spermatozoa. The symptoms of the chronic condition are chiefly those of a chronic posterior urethritis and sexual neurasthenia, with sterility.

In the acute stage the seminal vesicles can often be felt through the rectum as elongated fusiform, elastic bodies, just above the prostate. These are hot and sensitive to the touch. If the patient be instructed to pass the urine in three glasses, and between the voiding of the first and second specimens the contents of the inflamed sacs be expressed by the finger in the rectum, the second specimen will contain a larger amount of pus than the first or third, and also a number of dead spermatozoa.

The admixture of any considerable amount of pus with the semen almost invariably results in a death of the spermatozoa, or, at least, a serious impairment of their impregnating ability. This condition is, therefore, most important in its relation to marriage.

Treatment.—In the acute stage marked relief often follows the application of leeches to the perineum and hot rectal enemata. The bromides, with digitalis and camphor, in large doses, are useful in subduing the sexual hyperæsthesia. Absolute rest should be enforced, and applications of nitrate of silver be made to the deep urethra.

In chronic vesiculitis local measures are of little value, and dependence must be placed upon hygienic treatment, including sea-bathing, a change of climate, cod-liver oil, iron, and the scrupulous avoidance of stimulants and sexual excitement.

George Emerson Brewer.

GOERBERSDORF. This place is in Silesia, Germany, not far from the city of Breslau. It was here that Dr. Brehmer started, in 1854, his famous establishment for the treatment of consumption by mountain air, cold douches, diet, etc. Goerbersdorf is situated in a fairly well-sheltered valley, and has an elevation of seventeen hundred feet above sea-level. The climate is rather severe in winter, but the admirably arranged buildings permit exercise in pure air at all seasons. Apart from the institution of Brehmer, now in charge of Dr. Achtermann, there are two other sanitaria for diseases of the lungs, neurasthenia, etc., one in charge of Dr. Römpler, the other managed by the Countess of Pückler. The good results obtained at Goerbersdorf are now generally held to be due quite as much to the careful supervision of every individual and the attention to minute details of treatment, as to the climatic advantages of this locality. Season, all the year round.

Edmund C. Wendt.

GOLD. The use of gold as a remedy in disease is of very ancient date, although of late years it has fallen into disuse. Very recently it has been revived, and the various salts are recommended in many forms of nervous disease. Formerly it was used almost solely in the treatment of scrofulous and syphilitic disease. The action of the salts of gold is similar to that of mercury, being even more powerful when administered freely; salivation is produced, and prolonged use gives rise to "aurism," with sweating, increase of urine and saliva, and mental excitement, with delirium and intoxication. It is eliminated by the liver, intestines, and kidneys. It is still used occasionally for syphilitic troubles, and will often produce a cure where mercury and the iodide of potassium have been used without any apparent benefit. It is said to prove most efficient in syphilitic ulceration of the throat, ozæna, diseases of bones, and syphilitic phthisis. Its revival, however, is principally in the treatment of the various neuroses, hysteria, ovarian disease, sterility, impotence, hypochondria, etc. The beneficial effects of the use of the preparations of gold are most evident on the brain and nervous system, which is stimulated and ren-

dered more active, and, when the use is persisted in, the symptoms of this stimulation continue to increase until the toxic condition supervenes. The use of gold is indicated whenever there is depression of the central nervous system, and should be avoided when cerebral hyperæmia is present.

Auri et sodii chloridum, the official salt of the U. S. Pharmacopœia, has shown itself of service in nervous dyspepsia, in doses of one-twentieth grain, three times a day. Amenorrhœa from torpor of the ovaries, and chronic metritis with scanty menses, are often relieved. Bartholow has recommended it in sterility due to functional debility of the sexual organs. It has been used in the treatment of progressive general paralysis, in which affection it increases the patient's powers of resistance and retards the progress of the disease. It is given in doses of one-thirtieth grain, morning and evening. Every fortnight the dose is to be increased until one-sixth grain is reached. This amount is continued for another fortnight and then stopped for a month. This salt of gold was recently brought into prominence by its reported value as a means of treating pulmonary phthisis. Its use for this purpose was introduced by Dr. Heneage Gibbs who, with Dr. Shurley, had experimented upon animals and used it very extensively in their practice, and found it to prove of decided value. Its use is combined with the inhalation of chlorine gas and the hypodermic injections of iodine. The chlorine gas may be obtained from chlorinated lime by the addition of dilute hydrochloric acid, from one-half to six drachms of the former and from one to three drachms of the latter, in an open vessel in a closed room. Before the gas is produced the air should be impregnated with a spray of chloride of sodium, about two ounces in a compartment of five hundred and fifty cubic feet. The patient should only remain in the room for ten minutes at first, but this may be increased to twenty or thirty minutes. It may be repeated two, three, or four times a day. In laryngeal phthisis, or when it may prove more convenient, the gas may be evolved in an inhaler. The iodine and gold are introduced by means of an hypodermic syringe in the gluteal region. Iodine is used in one-twelfth grain doses daily, to begin with, and gradually increased until one-half to one grain is reached. The gold and sodium is then used, and hypodermics of one-thirtieth to one-twentieth grain daily are administered at first, the dose being gradually increased until one-fifth or one-third grain is reached. It is often necessary to discontinue one or the other, as "iodism" or "aurism" is threatened. They may also be used alternately. It is found that the combination of gold with the iodine allows a much larger amount of the latter drug to be administered without causing toxic symptoms. At first, loss of weight and increase of temperature and other signs of disturbance follow its use, but these soon disappear, and a marked improvement takes place. The authors of this remedy base their hopes of a successful treatment of this disease upon the view that consumption is not the same as general tuberculosis, and is not due to the generally recognized bacillus. They consider that phthisis pulmonalis is a local affection of the lungs of an inflammatory character, the progress of which is accompanied by the production of chemical substances which possess a toxic action. The object of the treatment is to neutralize these poisonous substances, allay the inflammatory process, and restore the vital powers. Chlorine, iodine, gold, iodoform, liq. potassæ, potassic permanganate, iron arseniate, the mercurial salts, were all found to possess these valuable properties, but the first three were selected as being the most efficacious and least disturbing to the system.

Auri chloridum occurs in long orange crystals. It is very hygroscopic and readily soluble in water, alcohol, and ether. It is a powerful caustic and enters into the composition of many cancer-pastes. As a caustic for epithelioma, one-sixth to one-quarter grain in powder may be rubbed into the affected part or applied in solution. A case of lupus is reported as having been successfully treated with the hypodermic use of chloride of gold and cyanide of potassium, a solution of the strength of one per cent. of each being employed. Nearly the whole face and forehead were involved, and tubercle bacilli were found to be present. Six injections were given in the course of eleven days, the dose varying from one-thousandth to one-hundredth grain. On the second day the symptoms showed signs of improvement; on the third day the swelling of the face subsided, some old scars began to shed cuticle, and a labial ulcer decidedly decreased; by the twelfth day several ulcers were soundly healed, and the remaining ones were clear and covered with healthy granulations. On the fourth day of treatment a mild intoxication, drowsiness, and a slight rise of temperature were noticed, but they rapidly disappeared.

Auri Bromidum.—This combination has been utilized to secure the combined effects of gold and bromine on the central nervous system. It is a dark brown, non-deliquescent powder, soluble in water and ether; dose, one-fortieth to one-hundredth grain, to be increased to one-fifth grain, well diluted. The solution should not be exposed to light. It has been used in hysteria, epilepsy, migraine, and the various affections of the nervous system in which the action of these drugs is indicated. In epilepsy it has acted very satisfactorily: the action of the drug was rapidly manifested, the fits becoming reduced in force and number, and in some cases they were completely checked. The introduction of this remedy caused Dr. Shtcherbok to undertake a series of experiments with the cerebral cortex exposed, to ascertain the action of the drug, its effect as compared with other bromides, and in what quantities it should be given. The drug was administered by intravenous injection, by hypodermic injection, and through an œsophageal tube into the stomach. It was found that artificially induced epilepsy could be averted by the intravenous injection of one-twelfth grain for each thirty-two ounces of body weight. Larger doses were required when used by hypodermic injection, and by the stomach one and one-half to three grains were needed. No cumulative action was detected. The drug seemed to affect mainly the tracts of communication between individual motor-cells, as well as those between remote areas of the cerebral cortex. Bromide of gold appeared more active than the commonly used bromides in the proportion of ten to one.

Other compounds, as the cyanide, iodide, oxide, etc., have also been tried for the treatment of syphilis, but with uncertain results. *Beaumont Small.*

GONORRHŒAL RHEUMATISM. Since the publication of the REFERENCE HANDBOOK many investigations and observations have been made to determine more accurately the pathology of this affection. The results have not been very decisive, except, perhaps, to settle more firmly the dependence of some of the cases upon the gonococcus. A number of investigators have found the micro-organisms not only in the urethra but in the joints as well, whither they had been carried by means of the lymphatics, the blood circulation, and possibly the white corpuscles. There is still reason to believe that some of the cases partake more of the character of ordinary septicæmia, although differing from it in certain particulars; while some are still, on any theory so far advanced, inexplicable.

In the management of this affection it has been proven more conclusively that it is necessary to remove all points of irritation in the urinary mucous membrane, even to the relief of stricture, that may have caused the affection, as a first step to its cure. Iodide of potassium as an internal remedy is still popular, as well as mercurials in moderation. Some advocate the latter in quantities sufficient to produce their constitutional effect promptly, at the beginning of the attack.

Counter-irritation over the inflamed joints by blisters and the actual cautery are becoming more popular, as are also stimulating embrocations, and heat.

In the original article on this subject, the violent breaking of old, false anchyloses, long after their formation, was commended as rational. Less has been done

in this line than was to have been expected. The measure deserves to be more often employed. On rational grounds it has much to commend it; the anchylosis is due to fibrous deposits; at most, rupture of this material should result in producing some débris of soft substance that is readily absorbed, and after it possibly a slightly roughened surface; and roughened joint surfaces after the disappearance of causative pathological processes, and with good nutrition, tend to disappear. Sepsis is, of course, impossible, except with a very low condition of vitality of the patient. Dr. B. E. Brodhurst declares that he has operated on a large number of cases of fibrous anchylosis in this manner without a single accident, such as fracture, dislocation, or inflammation. He forcibly breaks up the adhesions under chloroform. If contractures of muscle have occurred, he cuts the tendons before forcing the adhesions, and if the contracture is extreme, he waits for the skin punctures to heal before doing the joint operation. After the operation, passive motion must be resorted to to keep what has been gained.

Norman Bridge.

GOUT. In attempting to compile, in the form of a supplement, such facts and suggestions of importance concerning gout as have been developed by clinical and experimental investigators since the publication of the third volume of the REFERENCE HANDBOOK, containing the excellent article by Dr. Mendelson, I find nothing necessary to add regarding the history, varieties, and symptomatology of the disease. The additional materials relate almost wholly to its etiology, pathology, and therapeutics. To show more clearly the true relations and practical bearing of such new materials I have felt the necessity of repeating or restating many items that are to be found in the original article by Dr. Mendelson, instead of making frequent references to the same, which would be less convenient for the reader as well as for myself. Such restatements are chiefly in the beginning, and seemed desirable as an introduction to the mere facts that follow. The causes of gout, as of most other diseases, are conveniently divisible into predisposing and exciting causes. The first include all such influences as either aid in developing the direct exciting cause or in lessening the power of the system to resist the action of such cause. The second embraces only such agents or influences as are capable of directly exciting the active symptoms of the disease. The more important of the predisposing influences are: heredity; alcohol, especially as existing in fermented liquors, such as beers and wines; excess of food, especially of the nitrogenous class; deficient physical exercise; deficient ventilation; excessive mental exertion and depressing emotions, such as grief and anxiety; and lead. A careful study of the *modus operandi* of these various causes will render it apparent that heredity and continued severe mental activity produce their predisposing influence by increasing the susceptibility and lessening the vital resistance of the living tissues; while all the others act chiefly in the direction of lessening the internal respiration, or, in other words, the distribution of oxygen from the pulmonary to the systemic capillaries, and thereby interfering with the metabolic processes on which the formation of natural excretory products depends. That depressing mental emotions, deficient exercise, and poorly ventilated and overcrowded dwellings lessen the fulness and activity of respiration, and in the same ratio diminish the internal distribution of oxygen, has long been well known. That alcohol, by its action on the hæmoglobin and albuminous elements of the blood, still more directly diminishes the internal distribution of oxygen and thereby lessens the natural metabolic processes, has been abundantly demonstrated. It is not, however, diminished distribution of oxygen alone that favors the development of gout, but it is the co-existence of an abundant supply of oxidizable or fermentable material in the blood, such as is derived from overeating or the drinking of such fermented drinks as contain sugar, free acids, and other fermentable materials. Therefore it may be correctly stated that it is neither deficiency of oxygen alone, nor excess of either alcohol or fermentable material alone, but the co-existence of all three, that most directly favors the formation in the blood and tissues of an excess of uric acid and urates, and consequently most actively predisposes to attacks of gout.

The direct exciting cause of gout is very generally conceded to be the presence in the blood or tissues of an excess of uric acid, generally in combination with sodium in the form of bi-urate. Since the valuable paper of Dr. Garrod in 1848, much additional knowledge has been gained through the investigations of J. Mortimer Granville, W. Ebstein, A. Haig, Sir William Roberts, Cammerer, and others. As the uric acid in the form of urates of sodium and potassium constitutes a natural constituent of the fluids of the body, it is of great practical importance to know by what processes it is developed, through what channels it disappears, and the conditions under which it accumulates in abnormal quantities in the system. Uncombined uric acid ($C_5N_4H_4O_3$) is a crystalline substance, extremely insoluble, and derived from nitrogenous metabolism. Whether its evolution and combination with sodium and potassium takes place at some stage of the digestive and assimilative processes, or in some part of the retrograde tissue changes, cannot be regarded as definitely determined. Dr. Garrod, and perhaps a majority of writers on the subject since his original essay, have regarded the uric acid as only one stage of the processes by which nitrogenous tissues are resolved into urea for elimination. The uric acid being less oxidized and much less soluble than the urea, its accumulation was regarded as the result of incomplete oxidation of the products of tissue metabolism; a view strongly supported by the fact that very many of the conditions and circumstances that are known to retard the internal respiration or distribution of oxygen to the tissues are accompanied by an increase of the uric acid or urates. J. Mortimer Granville, however, claims that the uric acid is formed chiefly in the liver, from imperfect duodenal digestion. Regarding more particularly the clinical phenomena preceding and accompanying attacks of gout, he sees evidence of inactivity of the liver by which less bile passes into the duodenum to co-operate with the pancreatic fluid in saponifying the food-elements. In consequence of this defect the food-elements are taken up in only an emulsified condition and carried by the portal vessels to the liver, which so alters its glycogenic and other functions as to lead either to the "excessive formation of uric acid or to the arrest of the subsequent processes by which the acid should be converted or destroyed." On the other hand, W. Ebstein, of Göttingen, in his valuable treatise on the nature and treatment of gout, claims that the production of the greater part of the uric acid found in the living system takes place in the muscular structures, and to some extent in the marrow of the bones. In support of this claim he refers to the fact that such kindred bodies as kreatin, sarkin, and xanthin were found in muscular structures; to the deposits of uric acid in birds and reptiles, and to the guanine gout in pigs; and he might have added the presence of uric acid in cases of splenic leucocythæmia. That the production of uric acid in the system is increased by nitrogenous food, by such disorders of digestion as are accompanied by acid fermentation, and by whatever lessens the distribution of oxygen from the pulmonary to the systemic capillaries, has been well shown by the recent investigations of Dr. A. Haig, Lehmann, Sir William Roberts, and others; which renders it certain that it is derived from either nitrogenous food-elements or from the nitrogenous tissues, or more probably from both. And a careful review of all the facts within our reach leads to the conclusion that the uric acid is not exclusively the precursor of urea, but an independent product of nitrogenous metabolism undergoing elimination largely in the form of soluble urates, but in a lesser degree also as urea. The natural or physiological condition of uric acid in the body is that of a quadri-urate (Roberts), and not in a free or uncombined state. So long as it remains in the form of quadri-urate it is freely soluble in the blood-serum, synovia, and tissue fluids, and undergoes ready elimination through the kidneys, and consequently

it causes no disturbance or symptoms of disease. Concerning the history of uric acid in the living body, both in the normal and in the gouty state, Sir William Roberts, in his third Croonian lecture recently delivered before the Royal College of Physicians of London, says: "It has been shown that in normal urine uric acid always exists as a quadri-urate; and that in animals which eliminate their nitrogen as uric acid, like birds and serpents, the urinary secretion is composed entirely of the same combination. Proof has also been furnished that in liquids containing alkaline carbonates—such as the serum of the blood and its derivatives, lymph and synovia—uric acid passes into solution in the first instance as a quadri-urate. From these considerations it may be inferred that in the normal state uric acid is primarily taken up in the system as as quadri-urate, that it circulates in the blood as a quadri-urate, and that it is finally voided with the urine as a quadri-urate. In perfect health the elimination of the quadri-urate proceeds with sufficient speed and completeness to prevent any undue detention or any accumulation of it in the blood. But in the gouty state this tranquil process is interrupted, either from deficient action of the kidneys or from excessive introduction of urates into the circulation, or from some other cause, and the quadri-urate lingers unduly in the blood and accumulates therein. The detained quadri-urate, circulating in a medium which is rich in sodium carbonate, gradually takes up an additional atom of base and is thereby transformed into bi-urate. This transformation alters the physiological problem. The uric acid, or rather a portion of it, no longer circulates as the more soluble and presumably easily secreted quadri-urate, but as bi-urate, which is less soluble, and probably also less easy of removal by the kidneys."—(*The Lancet*, July 9, 1892.)

Pathology and Pathological Anatomy.—Assuming the correctness of the claim that sodium bi-urate constitutes the direct cause or disturbing element on which the various symptoms and forms of gout depend, what are the pathological processes and changes induced by its presence in the fluids of the body? It has been shown, both by experimental research and clinical observation, that the soluble quadri-urate naturally existing in the blood-serum and tissue fluids is readily changed into a less soluble bi-urate by failure of the kidneys to eliminate it, or by whatever will lessen the alkalinity of the blood-serum (Roberts), and by such food and drinks as either contain an excess of acid material, or give rise to acid fermentation in the digestive organs (A. Haig), thereby favoring the precipitation of such less soluble bi-urate in the tissues which are most favorable for its accumulation. That such precipitation does take place in all the more active forms of gout is readily demonstrable by both chemical and microscopic detection of its presence in the synovial and tissue fluids of the articulations affected, in addition to the well-known fact that it is the chief constituent of the tophi or gouty concretions found in the more chronic cases. According to Sir William Roberts, the precipitated bi-urate is always found in crystalline form, and is "distributed through the implicated tissue in the form of delicate needles aggregated in tufts, bundles, and stars." And he adds: "The arthritic incidents of gout may be said, not improperly, to be simply incidents pertaining to the precipitation of these crystals in the structures of the joints. Without the occurrence of this precipitation the gouty paroxysm could not take place, nor could the more chronic changes in the joints, with their train of attendant symptoms, follow after." From this we must infer that the offending bi-urate produces its effects by a primary irritating action, either upon the nervous structures or the fibrous tissues, or by mechanically obstructing the capillary vessels; or, perhaps, by all these modes simultaneously. When the quantity of bi-urate present is small and the precipitation slight, the chief symptoms are those of a neuralgic and erratic character without local tumefaction or febrile disturbance. If, however, its formation takes place more rapidly and it accumulates in greater excess, the precipitated crystals appear to penetrate all the tissues of the part involved, and to cause rapid tumefaction, intense pain, and general fever. In other words, it excites a true inflammation of all the structures permeated by its crystals. And if they are not subsequently redissolved, they become permanent obstructions inducing all the phenomena and changes incident to chronic gout. While the majority of investigators, including Garrod, Granville, Haig, and Roberts, regard the inflammation and other gouty symptoms as the result of the urate precipitation in the part, Dr. W. Ebstein claims to have traced, by numerous experiments and dissections, evidences of the direct irritative action of the sodium urate, both in the kidneys and other internal organs, and in the articular cartilages, fibrous structures, and the connective tissue between the muscles, thereby claiming to have proved the diffused primary action of the irritant conveyed in the blood before actual crystalline precipitation occurred. Consequently he regards the first stage of the disease as "an inflammatory process, set up by the uric acid, leading to foci of necrosis, and then deposits of urates in the cavities thus formed." He further endeavors to show that inflammatory necrosis in any tissue causes an acid reaction in the part, which acidity in turn determines the precipitation of urates in the necrotic foci.

The order of development of the pathological processes described by Ebstein necessitates a distinct stage of inflammation, or at least tissue poisoning, with its accompanying tumefaction and pain, before the precipitation of urates can take place, while careful and multiplied clinical observations seem to demonstrate the presence of the precipitated urate coincidently with the first manifestation of local symptoms. It appears, therefore, more correct to regard the necrotic foci described by him as resulting from the obstruction and irritation of the crystalline precipitate, instead of the latter resulting from the former. The more remote and full development of tissue changes induced by repeated attacks of gout are well set forth in the following account of a post-mortem examination by Hudelo, presented to the Anatomical Society of Paris (*Annual of Universal Medical Sciences*, vol. i., 1889), the subject having died from gout in the Hôpital de la Pitié, in the service of Troisier: "In the upper extremities tophi existed in the right hand at the base of the metacarpo-phalangic articulations of the index, medius, and ring fingers, and also at the base of the articulations of the second and third phalanges of the index and medius, and at the base of the thenar eminence. An incision through the integument near the thenar eminence exposed a soft, pulpy substance infiltrating between the muscles, and at the level of the fingers it filled the sheaths of the tendons without communicating with the articulations. By extending the incisions the uratic infiltration was found in the tendon sheaths of the palm of the hand. The articular cartilages of the phalanges and the metacarpal phalanges were covered with a whitish layer of urates. The periarticular bony contour was uneven, ragged, and in places presented osteophytic projections. The lesions were greatest at the base of the radio-carpal articulation. At the right elbow a subcutaneous tophus of the size of a hen's egg filled the olecranon pocket. The elbow-joint was filled with a mixture of synovia and urates. The hand, wrist, and elbow of the left extremity presented pathological and anatomical changes very similar to those described in the right. In the lower extremities the phalangic, metatarso-phalangic articulations of the tarsus and metatarsus of both feet were affected in the same manner as the corresponding parts of the upper extremities, the uratic infiltrations being most prominent in the articulations of the great toe. Both knee-joints were filled with the uratic deposit; the articular surfaces of both tibia and femur were diseased, their contour rough and irregular, with large osteophytes attached to the femurs. The surfaces of the patellas were also rough with osteophytic projections. The organs in the cranium and thorax were natural except the heart, which was large, its walls pale and thin, with dilated cavities, but without valvular deposits. Of the viscera of the abdomen, the liver was harder and more granular than natural, the pancreas contained a whitish substance re-

sembling the uratic infiltration, but not crystalline, and the kidneys were enveloped in an excess of fatty tissue, notably diminished in volume, the capsules easily removed, leaving the surface uneven, but with no appearance of cysts. Incisions showed marked atrophy of the parenchyma inclosing some fatty tissue. In the centre of the papilla was a series of whitish layers parallel to the collected tubes of the pyramids, but not extending more than six or seven millimetres into the parenchyma." It is thus seen that while the characteristic deposits and structural changes are most abundant in the less vascular structures entering into the articulations of the extremities, they may be found in less degree in nearly all the tissues and organs of the body. The deposits are always in the crystalline form, and composed almost exclusively of sodium bi-urate. Of the internal viscera, the kidneys suffer most, particularly from chronic interstitial nephritis characterized by the existence of an increased amount of interstitial connective tissue, with a corresponding atrophy of the secreting cells, thereby rendering the organs progressively less efficient in the performance of their natural function.

The changes in the fluids of the body during the existence of gout, are most noticeable in the blood, synovia, and urine; and chiefly consist of an increase of uric acid in the form of sodium bi-urate, instead of the natural sodium quadri-urate, as more recently determined by Sir William Roberts. Dr. Garrod has shown that an appreciable quantity of uric acid is pretty uniformly present in the blood-serum of chronic cases of gout. And Cammerer (see *Deutsch. Medicin. Wochenschrift*, March 5, 12, 1891) states that while the amount of uric acid in healthy blood is only 2.8 to 100 of urea, in those affected with gout it averages 3.1 to 100 of urea. M. Mollière, in a communication to the Lyons Medical Society in 1888, not only recognizes the increase of uric acid or urates in the blood in gout, but claims that it is antagonistic to both pyogenic micro-organisms and the bacillus tuberculosis; and alleges this as the reason why the gouty are so generally exempt from tuberculous disease. In most cases the hæmoglobin and red corpuscles are diminished. The synovia in affected articulations is often found turbid from the presence of urates.

The quantity of uric acid excreted in the healthy urine, in twenty-four hours, is about 0.5 gramme (grs. viij.), the greater part in combination with sodium. It has been shown by many investigators that for a day or two preceding, and at the commencement of, acute attacks of gout the urine is less acid and contains less urates than in health, but subsequently they appear in excess, especially at the crisis of the disease. Dr. A. Haig suggests that the diminished excretion of the urates at the commencement of acute attacks is owing to the fact that they are then being stored or precipitated in the tissues.

Such diminished excretion, extending even to a few days prior to the attack, may be further explained if we regard the views of Sir William Roberts as correct, when he states that the uric acid in healthy urine exists and is excreted in the form of soluble sodium quadri-urate, while in gout it has been changed to an insoluble bi-urate, and instead of continuing to be excreted, it is first retained and then precipitated in the tissues, and can only reappear abundantly in the urine after resolution, during the middle and advanced stages of the disease. To further emphasize this order of development, the same active investigator has designated the preliminary stage, while the quadri-urate is being changed into bi-urate in the blood-serum, synovia, etc., as the condition of *lithæmia*, and the succeeding precipitation into the tissues as *uratosis*.

Emil Pfeiffer, in a communication to the Seventh Congress of German Physicians, at Wiesbaden, 1888, claimed to have demonstrated that the uric acid in the urine of those affected with gout, even in the more chronic and latent conditions, could be separated in larger quantity by a certain process, while urine from non-gouty subjects did not yield any such increase: which, if true, would afford a valuable means of diagnosis, especially in the more obscure cases. His method consisted in obtaining all the urine passed in twenty-four hours, filtering it through paper and dividing it into two parts. One of the parts was again passed through a filter on which had been placed some chemically pure uric acid. The other part was not so treated. One hundred cubic centimetres from each of these parts were taken into separate vessels and acidulated with strong hydrochloric acid, and allowed to rest until the precipitated uric acid had completely separated. Then both precipitates were collected on previously weighed filters, washed with distilled water, dried, and weighed. If the urine had been passed by a person not affected with gout or urolithæmia, the two filters containing the dried products would show the same amount of uric acid; but if passed by a person affected by any stage of gout, the specimen that had been treated with the pure uric acid would show a notable increase of the dried product. Sir William Roberts subsequently repeated the experiments of Pfeiffer, and came to the conclusion that the test proposed was entirely unreliable. To this Pfeiffer has replied that the experiments of Roberts having been made with the urine of healthy persons, the results were not applicable, as the sole basis of his test was on the greater readiness of the urine of persons subject to gout to part with its uric acid. And as proof of such greater readiness of separation he alleges that, while from one hundred cubic centimetres of the urine of healthy persons the uric acid is only extracted by 2.0 or 3.0 grammes (30 to 40 grains) of uric acid, from the urine of gouty persons it is withdrawn by 0.2 or 0.5 gramme (3 to 8 grains). In this connection it is proper to state that Dr. C. J. Rademacher (see *American Practitioner and News*, Louisville, Ky., June 21, 1890) claims to have discovered a new acid in the urine of persons suffering from an attack of gout, which is precipitated almost immediately after having been voided, and which he regards as the direct exciting cause of the disease. He says, "this acid is only found in the urine during an attack of gout, and always in a free or uncombined state, while the uric acid remains in the urine as a urate and in solution."

His method of obtaining his new substance in separate form is as follows: "The precipitate in the urine was collected in a filter and washed with distilled water. It was then transferred to a beaker and neutralized with a dilute solution of caustic soda, and filtered through animal charcoal. The filtrate was treated with pure dilute hydrochloric acid, the precipitated acid again washed with distilled water, redissolved in a solution of caustic soda, and again precipitated with pure dilute hydrochloric acid, washed and dried. This acid, prepared by the above process, is a white crystalline powder but sparingly soluble in water. Its aqueous solution has a decided acid reaction to litmus (which uric acid has not); its formula, from ultimate analysis, is $C_5H_8O_4N_4$, its molecular weight 200, and it contains 28.28 per cent. of nitrogen." The value or correctness of the claim by Dr. Rademacher remains to be tested by further investigation.

Dr. Edward Grün, in *The Lancet*, London, January 23, 1892, makes the statement that "in three consecutive cases of acute gout he found the blood to be swarming with a long encapsuled bacillus, side by side with which numerous crystals of bi-urate of soda are to be seen," and promises more information in a future communication.

Treatment.—If the views presented in the preceding pages concerning the etiology and pathology of gout are correct, the objects to be accomplished by its treatment are easily inferred and capable of being clearly stated in few words.

The first object is to prevent the accumulation or retention of an excess of the normal sodium quadri-urate in the blood or tissue fluids long enough to favor its conversion into the less soluble sodium bi-urate, and thereby prevent the formation of the essential cause of the disease. The second object is to render the sodium bi-urate already formed in the blood and tissues more soluble and, consequently, more easy of elimination. The first object is essentially prophylactic or preventive, and the

means for its accomplisliment are almost exclusively hygienic in their character; while the second is directly curative or to relieve existing attacks, and the means for its accomplishment include the administration of such remedial agents as will increase the solubility of the biurate and facilitate its elimination through the natural channels, and such as may lessen its irritative action on the nervous and fibrous structures of the body. Few things within the domain of both clinical and social observation are better established than the fact that individuals and whole communities who have been trained from childhood to a fair amount of out-door muscular exercise, to the use of a fair variety of vegetable and animal food, and to total abstinence from alcoholic drinks, both fermented and distilled, are absolutely exempt from attacks of any form of gout. The only apparent exceptions to this rule are found in such individuals as have *inherited* a very strong predisposition from their parents. Such individuals, though habitually living within the hygienic conditions just stated, may be found to suffer occasionally with some form of neuralgic gout, but the number is very small.

The facts presented by Dr. A. Haig in his inaugural thesis, as well as those presented by many other writers, seem to show conclusively that a diet largely of animal food is accompanied by the excretion in the urine of less uric acid and urea than a diet chiefly of vegetables. Consequently the former is supposed to encourage the retention and storage in the tissues of the sodium urates, while the latter promotes their elimination, and has been generally regarded as more efficient in preventing their retention in such quantity as to endanger an attack of the disease. A careful study of such results of investigations and clinical observations as are on record seems to show that it is not profitable to attempt to adopt an arbitrary rule regarding the quantity or quality of food, at least so far as it relates to its nitrogenous or non-nitrogenous character.

The most important requisite is that the food shall be such as the individual eating it can most perfectly digest and assimilate without being accompanied with gaseous or acid fermentations, and yet will contain all the elements necessary for the repair of the solids and fluids of the body. That a mixed diet, composed of a reasonable proportion of meats, vegetables, and fruits, and taken not more frequently than three times in twenty-four hours, is that best adapted to promote the health and longevity of the human race, admits of little or no doubt.

The relative proportion of the three kinds of food, and the gross quantity to be taken, must be adjusted to the needs and capacities of each individual. And even when the food is thus adjusted, still another condition is necessary for its assimilation and normal uses in the living system, namely, the reception of the proper quantity of pure air, and the active distribution of its oxygen from the pulmonary to the systemic capillaries. Without this neither the metabolic processes concerned in digestion and nutrition, nor those of tissue metamorphosis and excretion, can be maintained in a strictly natural condition.

Consequently, constant access to fresh air and daily muscular exercise, not merely of the back and lower extremities, as in walking, but also of the chest and arms, by which fulness of respiration and freedom of pulmonary circulation are secured, are among the most efficient means for rendering the internal oxidation processes concerned in retrograde tissue metamorphosis complete, and thereby preventing the accumulation of an excess of sodium urates in the blood or tissues.

In addition to the proper regulation of the food, air, and exercise, still another hygienic condition is necessary to render the development of gout practically impossible, namely, the total abstinence from alcoholic drinks. The fact that the presence of alcohol in the blood so modifies the hæmoglobin as to diminish its internal distribution of oxygen and retard tissue metabolism, and so modifies the secreting functions of both liver and kidneys as to strongly favor the formation and retention of sodium urates in the system, is so fully established, both by experimental and clinical investigations, that it is not necessary to adduce the proofs here.

Neither is it important to enter upon the inquiry whether one kind of alcoholic drink *is* more injurious than another. All admit that the use of beers and wines is practically more efficient in producing and perpetuating gout than the use of distilled spirits, and for two obvious reasons: First, those who use chiefly the fermented drinks, use them more uniformly from day to day, and in much greater bulk; second, they take with them a greater amount of acids, sugar, and imperfectly fermented materials that directly encourage gastric, hepatic, and renal disorders. It is true, as so fully stated by Dr. A. Haig and others, that the use of food or drink containing free acids, sugar, and other readily fermentable materials, even without any alcohol, by persons already possessed of a strong gouty diathesis, either hereditary or acquired, may be sufficient to provoke a more acute attack. But, as already stated under the head of Ætiology, there is no proof that the use of any kind or amount of free acids, saccharine matter, or nitrogenous food will produce an acute attack of gout *de novo*, or develop the characteristic gouty diathesis without the coincident use of alcohol in some form. It is proper to insist, therefore, that entire abstinence from alcoholic drinks is necessary, both for effectually preventing the primary development of gout and for overcoming the diathesis when previously established. The medical treatment of gout in all its aspects should be directed for the accomplishment of three objects: first, to render the retained sodium urates more soluble; second, to hasten their elimination; and, third, to lessen the patient's pain and suffering while the two preceding objects are being accomplished.

For many years past there has existed a very general belief that certain natural saline or mineral waters, used freely for both drinking and bathing, were among the most efficient remedies for promoting the solubility of the urates concerned in the production of gout. Consequently several natural springs, both in this country and Europe, have become popular places of resort for the gouty invalid, and saline waters, artificial as well as natural, have been much prescribed by members of the profession.

Some, however, who have had ample opportunities for observation, deny their efficiency entirely, and attribute the improvements that patients frequently experience while attending at some of the most noted places of resort, to the change of air, diet, exercise, and rest from their usual occupations. Sir Mortimer Granville insists that the use of the same quantity of pure water is more efficacious as a solvent of urates than any water containing the salts of sodium, potassium, magnesia, or lithium. The correctness of his position is fully demonstrated by the results of an extensive series of experiments illustrating the chemistry and therapeutics of uric acid gravel and gout, by Sir William Roberts, as stated in his third Croonian lecture before the Royal College of Physicians of London, 1892, to which reference has previously been made. It is shown in the lecture that distilled water at the temperature of 100° F. will hold in solution 1 part of sodium bi-urate to 1,000 of the water, while water at the same temperature, holding in solution 0.50 per cent. of sodium chloride, and 0.20 per cent. of sodium bicarbonate —being about the same proportion naturally existing in blood-serum and synovia—would hold in solution less than 1 part of sodium bi-urate to 10,000 parts of the water. The experiments were so varied as to clearly demonstrate the fact that, the more salts having for their base sodium, potassium, magnesium, or lithium were contained in water at a given temperature, the less sodium bi-urate would be dissolved or retained in solution. And the result was the same whether the saline solutions yielded an acid or alkaline reaction with litmus. Similar experiments performed with the natural blood-serum and synovia led to exactly the same results. The important practical inference is, that the same liberal use of pure water, both for drinking and bathing, as is now made of the most popular mineral waters, would be productive of much

greater benefit, especially to all invalids of the gouty class.

For the speedy relief of paroxysms of acute gout colchicum has long sustained a high reputation. It should be given in as large doses as the stomach and bowels will tolerate, and repeated at intervals of from one to three hours until the pain and active symptoms begin to abate, when the doses may be diminished gradually, and finally withdrawn as soon as the relief is complete. If it acts too quickly on the bowels, as is sometimes the case, ten or fifteen minims of the acetated tincture of opium may be added to each dose. On the other hand, if the attack has been preceded by constipation, coated tongue, and scanty urine, from five to ten grains (0.31 to 0.61 gramme) of calomel may be given at once with benefit to the patient. As soon as acute symptoms have disappeared the further management of the case should be in accordance with the hygienic principles already stated for the removal of the gouty diathesis and the prevention of acute relapses, and only such medicines should be continued as may be necessary to maintain a healthy condition of the digestive and urinary organs. Dr. W. Ebstein, in treating acute symptoms gives, instead of colchicum, lithium salicylate in doses of 0.66 to 1.00 gramme (grs. x. to xv.), every two or three hours, until relief is obtained. Sir Mortimer Granville gives preference to the use of iodine, either in the form of tincture, iodoform, di-iodo-hydriodide of caffeine, or hydriodic acid, and claims that it unites with the sodium of the bi-urate and facilitates its elimination from the system. But he very properly says, it should not be administered in combination with sodium or potassium. Dr. C. J. Rademacher declares that a combination of colchicia, decandria, and solanin with iodine, constitutes a reliable specific remedy for gout.

The most recent remedy that has been highly recommended is piperazine. Dr. Schweninger, of Germany, is represented as having obtained most excellent results from its use in both acute and chronic cases (see *Journal of American Medical Association*, September 24, 1892). Drs. Biesenthal and Schmidt (*La Semaine Médicale*, No. 4, 1892) bear equally strong testimony as to its efficacy. It should be taken in dilute solution in pure water. One gramme (gr. xv.) may be dissolved in three hundred grammes (1 pint) of water, and the whole drunk during the twenty-four hours. At the beginning of acute cases, a larger quantity may be taken during the first day, but subsequently it should be continued for a considerable time in nearly uniform moderate doses, as its chief efficacy is supposed to consist in its power to increase the solubility and elimination of the sodium urates, and thereby counteract the tendency of the disease to continue in a chronic form, and to develop permanent arthritic uratic concretions.

Dr. Thomas A. Edison has reported a case of such chronic concretions successfully treated by electricity; while Dr. A. D. Rockwell reports one or more cases in which the use of electricity only hastened the dissolution of the tissues covering the concretions, instead of diminishing the latter. He has found electricity beneficial only in the chronic nervous manifestations of the disease.

Nathan S. Davis.

GRANVILLE. A sea-bathing resort on the coast of Normandy, and facing the shore of Brittany. It is a picturesque settlement, and, like many of the sea-side resorts in France, is divided into an upper new town and a lower old one. The principal hotels are the *Grand Hôtel du Nord*, *l'Hôtel des Trois Couronnes*, *l'Hôtel de France*, *l'Hôtel de Paris*, *l'Hôtel du Soleil*, and *l'Hôtel de la Boule-d'Or*, all of which are in the Rue Lecampion, and almost all of which have the same tariff of prices—viz., from 7 fr. to 8 fr. a day. The *Casino* of Granville is called *La Cabane*, and is a pretty, unpretentious little building in wood, on a terrace at the base of a high cliff. The beach, which lies immediately below this terrace, is of fine white sand, and terminates on the town side by a high, sombre-colored and picturesquely jagged cliff (Baughan, "The Northern Watering Places of France")

Steamboats ply between Granville and the Island of Jersey. Season, June to September. There are many fine walks and drives at and near Granville. The place is French, rather than international.

Edmund C. Wendt.

GRASSE. A winter health-resort on the Riviera, which has recently been made popular by the sojourn there of the Queen of England. The writer, after a personal inspection of the place, described it about as follows in the *Medical Record* of May 28, 1892:

Grasse is picturesquely perched on the southern slope of Mount Rocavignon, which rises some seven hundred feet above it. It is twelve miles by rail in a northerly direction from Cannes. The inhabitants, to the number of some fourteen thousand five hundred, are chiefly given over to the production of perfumery. Rose, cassia, heliotrope, violets, jasmine, verbena, jonquil, tuberose, orange, mignonette, and other blossoms are made use of in vast quantities for the purposes of this industry.

Grasse gets plenty of sunshine, but being inland and about twelve hundred feet above the level of the sea, its climate is tonic and soothing, rather than stimulating and exciting. It is a little colder than the Mediterranean coast places, but the rise and fall of the thermometer is less abrupt. It enjoys a more equable temperature than do some of the better known and more fashionable resorts of the Riviera. Grasse faces the sea, and enjoys a charming view over the lowlands running down to Cannes.

Spurs of the Esterel Mountains extend to the northwest, and in a northeasterly direction there rise the peaks of the Maritime Alps. The dust and mistral are less trying at Grasse than at neighboring winter stations, though the mountains back of the village fail to give it that complete protection which has been claimed for it. It will nevertheless be seen that Grasse possesses certain advantages that entitle it to be more patronized than it has been, at least by real invalids.

Not much has been done in the way of recent sanitary improvements. But the cesspool system is always less objectionable in small villages than in large settlements, where human beings are herded together in close quarters.

The Grasse drinking-water, while not absolutely irreproachable, comes from two good sources. It is conducted in canals, one of which is covered. It is safer to boil it before drinking, but it is less calcareous than much of the Riviera water. The two sources are known as *La Foux* and *Le Foulon*, and the supply is more than abundant. From the excellent little guide to Grasse, published by "An English Resident," the following table is taken:

ANALYSIS OF GRASSE DRINKING-WATER.—One litre of water taken at the sources contains:

	Foux.	Foulon.
Degree hydrometric	18.2 c.c.	18 c.c.
Organic matters calculated as oxygen from permanganate of potash	7.2 mg.	0.48 mg.
Chlorides	traces	traces
Nitrites and nitrates	nil	very slight traces
Combined ammonia and albuminoids	0.2 mg.	0.003 mg.
Oxygenation	8.5 c.c.	8.22 c.c.

The Grand Hôtel has been quite recently put in good sanitary condition by Mr. Best, of London. Board and lodging are cheaper in Grasse than at the more favored resorts. Many interesting walks and excursions offer themselves to the tourist. But apart from that there is very little "going on." It may be for this reason, perhaps, that so few Americans spend the winter at Grasse.

Invalids who do not prosper at the sea-side will do well to try the inland air of Grasse; and for some cases of nervous break-down the very dulness of the place should be a strong recommendation.

Cases of chronic laryngitis, pharyngitis, chlorosis, anæmia, and early cases of phthisis generally do very well at Grasse. Asthmatics and gouty patients are also benefited there.

Edmund C. Wendt.

GROUND ITCH. A disease so often met with deserves, at least, to be described and named. We can find no reference to it in the works on practice, on skin diseases, in encyclopædic handbooks, or the "Index Catalogue" of the Surgeon-General's Office; yet there is scarcely a boy raised in the coast districts of South Carolina who has not been a sufferer from this affection.

As it involves invariably one or more of the toes, seldom extending beyond them, and possesses the characteristics of eczema, there need be no difficulty in giving it its correct scientific designation. We would suggest the compound name, Eczema phalangis pedis.

Cause.—It is generally found in those going without shoes, and is popularly ascribed to walking barefoot in the sand, dew, and wet grass, and therefore generally affects boys.

It is met with extensively along the seaboard, in the Pineland residences, and elsewhere, also on Sullivan's, Pawley's, and other islands; and in these localities are found certain grasses armed with spines or prickles, which are highly irritating, though no complaints are made of them. Those of cleanly habits are not exempt from the disease.

Symptoms.—There may be at first moderate redness or subacute inflammation, followed by papules or vesicles which burst. This is accompanied by intense itching and burning, only partially relieved by scratching; the result being a sore with whitish ulceration around and between the toes, with a moisture characteristic of eczema. There is no rash, fever, or chill; no extreme swelling or sloughing.

It is analogous with an affection known as "stone bruise," quite common in the upper and more rocky districts.

The disease we are describing is neither camp nor prairie itch, nor is it embraced under any of their synonyms, which are all contagious and generalized over the whole surface of the body, whereas ground itch is strictly localized and never contagious.

A correspondent who is a high authority on dermatology suggests that "it is possible that it may be due to the attack of the pulex penetrans (sand-flea or jigger). This attacks the neighborhood of the toes, but is not commonly met with outside of tropical countries, although it has been reported from time to time as met with in the Southern States. Even though it be an eczema, it must, from your note, have peculiar features." We are inclined to dissent from this opinion, though we have heard the affection ascribed to some minute insect. Were the pulex the cause, it would be more readily recognized, for the female, which is generally regarded as a true flea, penetrates the thin skin between the toes or about the toe-nails, and then swells up to the size of a flea, forming a bag of eggs, and this becomes plainly visible. This causes much irritation, which often results in suppuration, followed by open ulcers.

Treatment.—There are many popular remedies, as, for example, bread-and-milk poultices in the early stages; soaking the feet in hot water is said to arrest the disease; applications of the leaves of the gourd or calabash (*Cucurbita lagenaria*) heated; a hot decoction of the yellow gerardia (*Gerardia flava*), which grows abundantly here and is considered a sovereign remedy. We have experienced good results from the application of a powder of aristol, bismuth, and oxide of zinc, equal parts. A combination of campho-phenique and oil or vaseline, equal parts, also gives great relief, and we have seen benefit follow the application of an ointment given us by the late Dr. Valentine Mott, of New York, for eczematous affections, viz.:

℞. White precipitate of mercury..... ʒ j.
Oil of tobacco .... gtt. x.
Lard..... ʒ j.

Iodoform in the moist stage is a useful application; and a strong solution of soda, frequently applied, relieves the itching temporarily.

When the suppuration is subsiding any drying powder, such as calamine, subnitrate of bismuth, oxide of zinc, or powdered cinchona bark, will prove useful. A medical friend finds equal parts of ichthyol and vaseline the most efficient remedy. Carbolic acid is sometimes employed as an ointment, with lard or vaseline.

The disease is often very refractory, the itching and burning being very severe. A patient, under constant supervision, is now in the sixth week of the disease.

F. Peyre Porcher.

GUAIACOL. This compound constitutes from sixty to ninety per cent. of creasote, and may be separated by fractional distillation, the portion passing over between 200° and 205° C. being collected. Chemically it is monomethyl pyrocatechin, with the formula of $C_6H_4OHOCH_3$. It is a colorless liquid with a strong, aromatic odor, very slightly soluble in water, 1 part in 85, but readily soluble in alcohol and ether. Specific gravity at 60° F., 1.117; boiling-point, 200° to 202° C. Guaiacol may also be formed from guaiacum resin by distillation. Many of the guaiacols of commerce are contaminated with various impurities, which give it a lower specific gravity and boiling-point; they are darker in color, and spoil by exposure to light. With concentrated sulphuric acid the pure guaiacol gives a faint yellow coloration, which is changed to a yellow red by the addition of a small quantity of acetone; the impure guaiacol gives a more or less red color with the acid alone. A characteristic test for guaiacol is the addition of a trace of ferric chloride to an alcoholic solution: this gives a blue color which changes to green with the presence of a greater proportion of the salt. Guaiacol is excreted with the urine, the saliva, and the perspiration, and may be detected as early as half an hour after its administration. It may be demonstrated by distilling the secretion with diluted sulphuric acid. The product is placed in a test-tube and to it is added a small quantity of highly dilute solution of liquor ferri sesquichlor. (two or three drops to a test-tube of water). In the presence of guaiacol a reddish-brown color is gradually developed, the intensity of which is in proportion to the amount present.

The value of guaiacol in the treatment of tubercular disease was pointed out by Professor Max Schueller, of Berlin, in a work published in 1880.[1] The author had made numerous trials, with various drugs, upon animals affected with tuberculosis. Extract of guaiacum wood, guaiacol, creasote, benzoate of sodium, and many other substances had been experimented with, and he had selected guaiacol as the most serviceable. In 1891 a second treatise was issued,[2] reviewing his work during the intervening years and explaining in detail his method of employing the drug in general and in surgical tuberculosis. Dr. Schueller administers it continuously for a long period in moderate doses; he does not think large doses are of any special value. An improvement shows itself quickly, but the remedy must be continued throughout the course of the disease, and when recovery takes place its use must be persisted in for some time longer. He particularly insists upon it being given for some months after the bacilli have disappeared. He has recorded eighteen cures of pulmonary tuberculosis; some of the patients have been free from symptoms of returning disease after several years have elapsed.

In pulmonary tuberculosis he gives it in doses of two or three drops to children, and three to five drops to adults, four times daily. He gives the drug without any preparation, in a glass of water, to which a little table salt has been added to facilitate solution and cover the taste; or it may be given in milk, wine, or spirits. He does not like the use of pills or capsules. This method, he thinks, allows it to be present in the stomach in a too concentrated state, but where such are given, large quantities of water should be used before and after to facilitate solution and dilution. Guaiacol is well borne by the stomach, and its disagreeable odor and taste are soon overcome to such an extent that patients rarely complain.

Dr. Schueller has also used it extensively in surgical tuberculosis with equally satisfactory results. It is admin-

istered internally as in pulmonary disease, and injected into the site of the local trouble. He also uses the guaiacol in combination with iodoform for the local treatment. Enlarged glauds, tubercular deposits, and skin affections in which caseation has not commenced, he has seen disappear with simply the constitutional treatment, and many threatened joint affections have been averted. In tubercular disease of the bones, when caseation and destruction have taken place, he considers that the diseased tissue should be removed, and the local use of guaiacol and iodoform then proceeded with to promote repair and prevent the return of the disease.

Guaiacol has been very extensively used as a substitute for creasote, and has been found to be easily taken and retained. It is also of a more definite strength than creasote, and free from any deleterious effects. The dosage varies, and many follow the method of Sommerbrodt with creasote, in giving large doses and pushing it with the idea of saturating the system. It is generally given in solution in preference to other ways, and tincture of gentian, tincture of cinchona, and wine, are favorite menstrua with which it may be combined, to disguise its taste and increase its tonic action. If for any reason it cannot be administered in the ordinary way, it may be given in the form of an enema, and for this purpose the following formula may be adopted: Guaiacol, 7 grains; sweet almond oil, 1½ drachm; gum acacia, ¾ drachm; distilled water, ½ pint.

Iodoform in combination with guaiacol, as an improvement upon the latter alone, was introduced by Professor Picot, of Bordeaux.[3] A solution of the two drugs in sterilized olive oil is prepared and used subcutaneously. The dose he advocated was very small, viz., one-sixth grain of iodoform and one grain of guaiacol, daily, to be increased gradually until three times that amount is reached. He selected the supra-spinous fossa as the most suitable place for the injection, as it does not bear the weight of the body when the patient lies on his back. No local reaction followed its use, but from twenty to thirty minutes after the injection signs of a general reaction were evident; there was profuse perspiration of the face and chest, which was followed by a lowering of temperature. The digestion was not affected, but in some cases colic and diarrhœa were complained of. No effect on the urine was noticed. Twenty-five cases of tubercular phthisis and pleuritis were treated, and Professor Picot had never obtained such favorable results in any other line of treatment as he observed in these cases. He sums up as follows: The injections improve the general condition, and lessen cough and expectoration. In certain cases they dry up cavities and favor their cicatrization. In the second stage of phthisis they make cough and expectoration disappear, while causing the cessation of fever and night-sweats. They also diminish the number of bacilli in the sputum. Professor Picot, at a later date,[4] reported the results of forty-two cases treated with the same satisfactory results, and without any unfavorable symptoms accompanying the injections.

Dr. R. Robertson, at the British Medical Association, 1891,[5] gave the result of his experience. He used it after the manner of Professor Picot. The small dose was commenced with, at the seventh day it was doubled, and at the twenty-first day the full quantity was begun. He employed the remedy in twenty-five cases of consumption and three of empyema. He concludes, 1, that in empyema with free drainage the treatment does good in improving the general condition and in diminishing the discharge from the pleural cavity, but that without free drainage it is of uncertain value; 2, that in pyrexic phthisis, whether the disease is small in extent or so extensive that the case seems almost hopeless, it is not an absolutely certain antipyretic, but it is commonly of decided advantage, if persevered with, in reducing the fever, and by so doing in diminishing the activity of the disease; 3, that even where it fails within a reasonable time to modify the fever, it is still serviceable in most cases in diminishing expectoration and in modifying the cough; 4, though it is serviceable in limiting waste by reducing temperature and by diminishing expectoration, it cannot be said that this treatment is specially favorable to increase in body weight; 5, the treatment is without risk with ordinary precautions; 6, its use does not prevent the development of other tuberculous outbreaks or extensions of tuberculous mischief, for meningitis, pleurisy, hæmoptysis, have been shown to occur after many injections; 7, in interpreting the mode of action of these remedies, their antiparasitic action should not exclusively be thought of; it must not be forgotten that both remedies act upon the patient himself, even in small doses, as a sedative, as a stimulant of the mucous membrane, and as an astringent.

Benzosol.—A crystalline salt of guaiacol in which an hydrogen atom of the hydroxyl group is replaced by benzoyl. It is the benzoate of guaiacol. The chemical formula is $C_6H_4OCH_3OCOC_6H_5$. It is a colorless crystalline powder, almost devoid of taste and odor, insoluble in water, readily soluble in alcohol, ether, and chloroform. It contains fifty-four per cent. of guaiacol. The boiling-point should not be below 44° C.

Benzosol is acted upon by the alkaline secretions and gradually decomposed, guaiacol and benzoic acid being formed. It does not cause any irritation to the digestive tract nor give rise to eructations or any other disagreeable symptom. Its advantage over guaiacol is the absence of any odor and taste. In addition to its use as a substitute for guaiacol in the treatment of phthisis, it is also recommended as an intestinal antiseptic where such is required. The dose is four grains, to be gradually increased to twelve grains, three times daily.

Guaiacol Carbonate was also introduced[6] because it afforded a better means of administering guaiacol than the employment of the parent liquid afforded. It has the advantage of being more definite in composition and perfectly free from any adulteration. Although termed a carbonate its formula is $CO(OC_6H_4OCH_3)_2$. It forms in neutral crystals, is tasteless and without odor, and is insoluble in water. Its melting-point is 86° to 90° C. It is not affected by the gastric juices, but in the alkaline secretions of the intestines it is decomposed and guaiacol set free. If the stomach is deranged and the seat of putrid fermentation, the decomposition of the salt will take place and produce its beneficial action. It is also used to replace guaiacol and creasote in phthisis. The dose is six to eight grains, gradually increased, three times a day. As much as ninety grains have been given without producing disturbance of the digestive organs.

Guaiacol Salicylate, also called guaiacolic salol. Its chemical formula is $C_6H_4OHCOOCH_4OCH_3$. It occurs in white, odorless crystals, with a melting-point of 65° C. It is insoluble in water. This compound is introduced for the same purpose as the above salt, and is also said to be much superior to salol for all purposes in which that salt is employed. The dose and modes of administering are the same as for salol.

HÆMOGALLOL. A patented article prepared by the reducing action of pyrogallol on the coloring matter of the blood, It is a brownish-red powder, very soluble, and more readily absorbed than any other preparation of iron. It is very well borne by the most delicate stomach, and when absorbed is easily transformed into the blood coloring matter. The dose is from two to eight grains, three times a day. As much as fifteen to thirty grains have been given without any inconvenience.

This compound was introduced by Professor Kobert, Director of the Pharmacological Institute of Dorpat University, as the result of a series of experiments upon the assimilation of iron salts. He considers that ferruginous preparations, if they are of any value, should be excreted

with the urine, not immediately, but after the lapse of a few days, and should appear as a definitely formed urate of iron. None of the usual preparations of iron answer to these conditions. When introduced into the blood they are excreted to the extent of forty per cent. in an unchanged condition, which would indicate that the assimilation of these salts is very uncertain. The new preparation answers to all the above conditions, and clinical experience has shown the most favorable results, both in chlorosis and anæmia.

Hæmol is a similar preparation, obtained by using zinc-dust in the place of pyrogallol as the reducing agent. The dose is the same as that of hæmogallol, the action is very similar, and the same favorable results have been obtained. This preparation contains a trace of zinc, which is considered a rather desirable combination, as it exerts a beneficial action where there are lesions of the stomach or intestines. *Beaumont Small.*

HAND, DEFORMITIES OF. ATHETOSIS.—No local treatment, either mechanical or operative, of the deformity associated with athetosis has given satisfactory results. Relapses have invariably occurred after even prolonged immobilization, and after section of the tendons deformity has soon recurred and become steadily worse. Only excision of the cerebral cortical centres, which, of course, paralyzes the part, affords any relief to the deformity.

DROP-WRIST.—Very many cases of drop-wrist that obtain little, if any, benefit from other forms of treatment, go on to a partial, and not infrequently complete, cure when the nerve inflammation has subsided, by being persistently kept for a very long time in an over-corrected position.

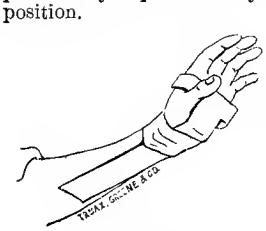

FIG. 210.

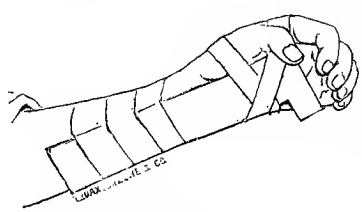

FIG. 211.

FIGS. 210 and 211.—Splint for Drop-wrist.

The hand is fully extended on the forearm and held by a simple metal splint applied to the palmar aspect, from the elbow to the carpo-phalangeal articulation. This position is maintained, without being even once relaxed, for from twelve to eighteen months. Structural shortening, the result of the position, seems to take place in the extensor muscles, and even if voluntary motion in them is not regained, the deformity is cured, and the flexor muscles act to a greater advantage, while a more comely and useful hand is the result.

INFANTILE HEMIPLEGIA.—In some cases treatment is of no avail; in others much restoration of function can be gained. If the deformity can be readily overcome, and the hand placed in the extreme opposite deformity without discomfort to the patient, it should be so placed and held by a suitable splint, without change of position, for from twelve to eighteen months. This overcomes the shortening of the flexor muscles and permits the slack of the extensor to be taken up by structural shortening. If the hand cannot be easily and comfortably placed in hyper-extension, division of all shortened tissues should be made, and the hand at once placed in the desired position and held there as already directed. A permanent gain in position may always be anticipated, and in a few cases there has been considerable restoration of voluntary movement. *John Ridlon.*

HASTINGS AND ST. LEONARD'S. Popular sea-side resorts and winter stations in Sussex, England. Hastings and St. Leonard's are practically one. They are at present fashionable winter stations rather than summer resorts, although the beach is remarkably fine. According to Black ("Watering-places of England, Scotland, and Ireland") the "ridge of hills that runs through the centre of Sussex divides at Hastings, as it approaches the sea, into several spurs, enclosing valleys, from within which begin the houses of Hastings and St. Leonard's, and extend to the beach, where they all join into one almost continuous frontage of about two miles. This frontage begins at St. Leonard's on the west, with one range after another of fine mansions, till Hastings is reached. Along the whole of this front extends one almost unbroken promenade. Behind, at various distances, are the cliffs, which are much lower at St. Leonard's; but from thence, gradually though irregularly, they increase in height till they attain the magnificent elevation, at or little beyond the eastern extremity of Hastings, of five hundred and sixty feet."

The east winds are at times very trying, but in general the climate is mild and equable, and for this reason many consumptives spend the winter there. There is comparative absence of fogs, and the porous soil quickly absorbs moisture. The drainage and drinking-water are good. The sanitary condition of the towns is excellent, the annual death-rate being only about sixteen to seventeen per thousand. There is a large pier at Hastings, with conveniences for exercise under glass-covered promenades. According to Savery ("Hastings and St. Leonard's, their Meteorology and Climate"), the whole number of fine days is 189. They advance with great regularity from their minimum in January to their maximum in July, and then as steadily decrease. The cloudy-fine days number 46; the cloudy, 52; the fine-rain, 42; and the cloudy-rain, 30.5; while the rainy days only amount to nine in the year. From this it is evident that the number of days on which the invalid cannot get out on account of the weather is very small; and those on which he may enjoy the rays of the sun, so conducive to health and vigor, are 280. To these must be added 52, which are dry though overcast; hence there are 332 days in which a person may enjoy a walk. The regularity of these results, and the small amount of variation year after year, is very remarkable, and has much surprised him, as the fickleness of the weather in England has passed into a proverb. Dr. Mantell claims that it is not necessary for the invalid, however delicate, to be confined to the house for any length of time. Apart from Torquay, few English resorts are better adapted for an invalid's winter residence than Hastings and St. Leonard's. Many excursions can be conveniently undertaken from these resorts. There are the usual concerts, assemblies, and other amusements. The hotels are good; the *Queen's* on the Parade, facing the sea, the *Albion*, and the *Castle* are the best. At St. Leonard's, the *Royal Victoria* and *South Saxon* are the best. *Edmund C. Wendt.*

HEADACHE. Since the appearance of the REFERENCE HANDBOOK very little has been added to our knowledge of the pathology of headache. There has been a good deal of speculation, and some ingenious theories have been suggested in explanation of some of the phenomena; many facts have been observed and classifications made without giving grounds for much change of views as to the nature of the trouble.

It is pleasant to note that so painstaking a student as C. L. Dana, after a thorough review of the whole subject, holds, with the original article on this subject, that we have no proof that headache may have its seat in the brain, although there is no proof that it may not. The cortex "may be the seat of headache, but then it is a psychical pain and in the nature of an hallucination." There can be no subjective difference between a genuine pain and one founded on an hallucination; to the patient they are identical.

Most headaches are doubtless in the nature of neuralgias of the nerves of the dura mater or of the tissues covering the skull. Of course this includes the tri-facial

nerves, the upper cervical nerves, and some sensory branches of the vagus.

The explanation of reflex headache has, like that of all reflex phenomena, been unsatisfactory. Why, for example, does an irritation of the stomach produce headache, instead of a pain in the foot? Dr. Dana suggests the theory that the first irritation being received by the vagus and transmitted to the brain is easily "shunted off or diffused" from the seat of original irritation to the nerves most obnoxious to pain. This theory is rational so far as it goes, but does not explain the special irritability of the headache nerves.

The explanation of migraine is still sought in the assumed discharge of nerve-force occurring periodically, a most unsatisfactory theory, but perhaps the best one at present. As illustrating the protean forms in which migraine appears, one author quotes ten cases—cases occurring at random—in which were represented the following symptoms: Concentric retraction of the field of vision, aphasia, hemianopsia superior, numbness of one arm, vertigo, agraphia, scintillating scotoma, hemiparesis, hemianæsthesia, difficulty of speech, amaurosis, and epileptiform convulsions.

Dana classifies two hundred cases of non-migrainous headache, and attributes thirty-five per cent. to poisons and poverty of the blood, such as anæmia, dietetic states, infections, uræmia, lead, alcohol, tobacco, etc.; twenty-five per cent. to reflexes from the digestive organs; ten per cent. to other reflexes; five per cent. to local organic disease, and twenty per cent. to neurotic states.

Much has been insisted of late on dull frontal and diffuse headache as resulting from catarrhal states of the upper part of the nasal passages, but I am satisfied that this is a much over-estimated cause.

The character of the headache doubtless indicates to some degree the causation; for example, the throbbing headache, aggravated by a jarring of the body, is more likely to be migraine, while the dull, steady pain is more likely to result from dyspeptic disturbance and toxæmia. The hot, burning, sore headache is often alleged to be due to anæmia, but frequently results from neurotic conditions incident thereto, and to uterine disorders. The intense, boring pain (clavus) is nearly always a hysterical symptom; while the occipital pain is often caused by eye-strain.

Weir Mitchell has wisely emphasized the fact that headaches probably often persist long after the causes of them, such as eye-strain, have been removed, as though from a habit of pain. They are more likely to persist when they have come on during the period of youth.

Sunstroke leads often to persistent tendency to headache, always aggravated by heat, and especially by the sun's heat. There can be no doubt that in some of these cases, as well as in cases following injuries, spots of meningeal thickening occur which through pressure on nerve-fibres and abbreviation of the movements of the brain substance, as well as possibly by reflex action, lead to almost constant pain.

Each year fresh evidence develops of the manifold headaches due to eye-strain from various optical defects of the organs of vision, the variations of hypermetropia and astigmatism being the most common. Defects of the extra-ocular muscles probably also cause headache. Observers differ as to the proportion of cases due to these causes all the way from a modest figure up to seventy-five per cent. or more. A misleading circumstance is the fact that in some of the worst of such cases there are no ocular symptoms of pain or discomfort.

Experience shows that oculists have not yet found the way to correct by glasses all cases of headache due to optical defects. Many cases must be tested repeatedly and experimented with in the use of various degrees of correction before the right fit is found; and sometimes the right fit is not found, suggesting that such cases are not due to the eyes. This conclusion is less tenable since numerous such cases have, by later methods and more careful testing, been entirely relieved.

The claim has been lately put forth, and defended with zeal, that headaches, as well as other nervous troubles, including epilepsy, are often due to inequality or asymmetry in tension of the extra-ocular muscles, for which graduated tenotomy is recommended. Many operations of the kind have been made, but the results have not been such as to commend either the theory or the remedy to the majority of students of the subject. That there is a measure of truth in the theory is probable, but its advocates have unquestionably claimed too much for it.

Within a few years a remarkable series of coal-tar products of the chemical laboratory have come into use in the treatment of headaches, as well as of neuralgias in general. Antipyrine has been used most extensively, while antifebrin, or acetanilid, and phenacetine, have been used very widely. Exalgine has been used to a limited extent. Various secret and proprietary preparations, which are mostly compounds of some of these medicines with various modifying agents, have also been extensively employed. So common has the use of this new class of agents come to be in the United States, that many people purchase and use them on their own responsibility as freely as quinine is used for so-called malaria. Notwithstanding the wholesale use of such medicines, very few unfortunate results have been recorded.

Antipyrine is a fine crystalline white powder, highly soluble in water, while antifebrin is offered in coarser crystals, and is sparingly soluble in water; phenacetine is similar in appearance, and is also sparingly soluble in water.

These agents were first introduced as antipyretics, but were found to exercise a potent influence upon the nervous system, particularly in the presence of simple neuralgias, especially those that are produced by reflex influences and aggravated by the lowering of vital tone.

Antipyrine has been used in doses of two to twenty grains, and but few instances have been recorded of injury from this larger dose. Occasionally a large dose produces a sense of prostration, evidence of heart weakness or some skin eruption, but in general it may be said that in tentative quantities the drug is a safe one, even in the hands of the laity. The proper dose of antipyrine for headache in an adult is five grains, which may be repeated every half hour or hour until relief has been obtained, or until enough doses have been taken to prove that the drug is ineffective.

People differ widely in their susceptibility to the remedial influence of the drug for headache, but most persons experience benefit from one to three doses of five grains each; but some seem not to be affected by any safe quantity of the drug. Doubtless the cause of the headache determines to some degree the susceptibility to the remedy; thus true migraine headaches, produced by digestive derangement and fatigue of the eyes, are more likely to be benefited than headaches due to nephritis, anæmia, nervous exhaustion, and cerebral syphilis. One trial of the drug will nearly always determine for each patient its constant effect upon him. A headache relieved by a certain dosage for a particular patient may be expected thereafter to yield, to some degree, to the remedy, but migraine patients have found that they acquire a tolerance for the drug that makes it, after repeated trials, ineffectual except in large quantities; so that many, after a year's trial of it and more or less benefit, have rejected it as unsatisfactory. This has been, however, the experience of such patients with every drug known to affect the disease.

Antipyrine seems specially applicable to cases of headache produced by gastric disturbance; in many cases it corrects the stomach disorder as well as the headache; and if taken at the first appearance of the premonitions of a migraine it may cut these symptoms short and prevent the appearance of the paroxysm. An effective and convenient way to administer the drug is by means of compressed tablets.

Antifebrin should be given in smaller doses than antipyrine. It produces much the same effect, but is less soluble in the stomach, and, given in large quantities, as twenty or thirty grains within a few hours, it is liable to produce a cyanosis, due to an effect upon the superficial capillaries. This condition is known not to be specially

dangerous, but is generally alarming to lay people who observe it. This drug has not given the satisfaction to patients with headache that has been experienced from antipyrine and phenacetin. Probably one explanation of this fact is the sparing solubility of the remedy. The drug is much more soluble in hot water than in cold, and may well be given in a hot solution where its prompt action is important.

Phenacetin produces fewer unpleasant symptoms than antifebrin, is very popular with patients who have used it for headache and neuralgias, and may be given in about the same doses as antipyrine. It produces more perspiration in febrile cases than either of the other drugs named; and in large doses may produce decided cyanosis. It is unwise, however, because of its sparing solubility, to give this drug in the shape of compressed tablets, if there is any considerable catarrh of the stomach. I have known such tablets given in typhoid fever for headache to pass in large number through the alimentary canal undissolved.

Just how these drugs act is something of a mystery. Antipyrine is believed by some to reduce intra-cranial blood-pressure, and that it should never be used when spasm of the blood-vessels exists—if it can be known certainly when that occurs, of which there is often some doubt.

There is no reason to think that any of these new remedies induces a lessening of the tendency to regular recurrence of migraine paroxysms. *Norman Bridge.*

HEART, THE. The vertebrate heart arises in two distinct ways, each of which is intimately associated with the origin of the blood-vessels in general. In the lower vertebrates its first appearance is in the form of a single tube on the ventral median line of the embryo, quite near the head. Fig. 212 is a section of a salamander embryo in which the heart is just beginning to form. The body cavity *lh* is composed of two lateral halves (see *Cœlom*) separated from each other by a median septum. It is in this septum that the heart first makes its appearance. The two layers which contain this septum become separated, and the opening soon becomes lined with a layer of cells, *end*, the endocardium. The cells of the septum surrounding the opening give rise to the muscle-walls of the heart.

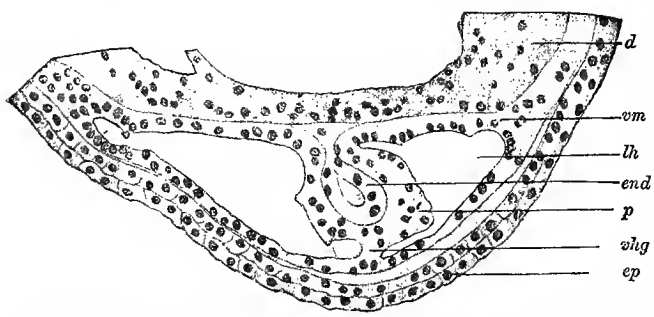

FIG. 212—Section through a Salamander Embryo, to Show the Origin of the Heart. (From Hertwig, after Rabl.) *d*, yolk; *vm*, pericardium; *lh*, body cavity; *end*, endocardium; *p*, muscle layer of the heart; *ep*, epidermis.

In higher vertebrates the heart is first formed by the union of two tubes arising from what might practically be called the outside of the body. Fig. 213 is a surface view of quite a young rabbit embryo in which the heart is beginning to form on either side. The omphalomesenteric veins on either side run toward the ventral median line, and later on unite. Their appearance is such, however, that before they are united they may be spoken of as two hearts. Fig. 214 is a section through an embryo of the same stage as that pictured in Fig. 213. The neural canal, *rf*, is just beginning to close and in the splanchnopleur on either side there is a large fold, *ahh*,

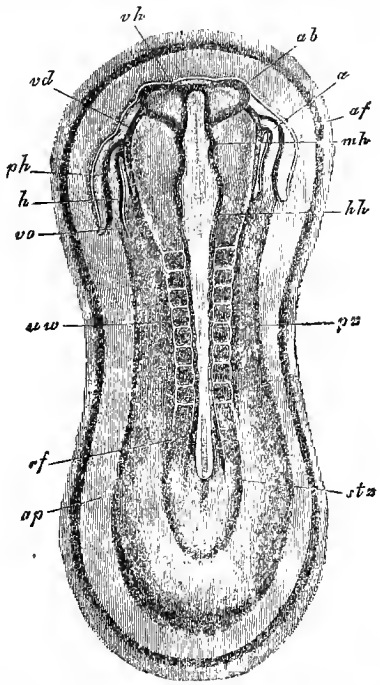

FIG. 213.—Rabbit Embryo of the Ninth Day. (After von Kölliker.) × 10 times. *h*, double origin of the heart; *ab*, optic vesicle; *vh*, forebrain; *mh*, mid-brain; *hh*, hind-brain; *rf*, medullary groove; *uw*, myotomes; *h*, heart; *vo*, vena omphalo-mesenterica.

which already contains the endothelial tube coming from the omphalo-mesenteric vein. The tubes grow toward the median lines, but before uniting each has its descending aorta, as shown in Fig. 215. The rudimentary hearts are formed between the splanchnopleur and entoderm, and as the former surrounds the heart to form its muscular layer the heart protrudes into the cœlomic cavity (Fig. 214), much as does the unilateral heart of lower vertebrates (Fig. 212). Soon the two halves unite as indicated in Fig. 215, and then we have a single heart with two veins entering from behind and two arteries, aortæ, leaving from in front. Although this primary division has nothing whatever to do with the later separation of the heart into its two halves, yet before the two primary hearts are united into a single tube the position of the ventricle is already marked (Fig. 215, *h*). So, to sum up, in the lower vertebrates the heart appears as a single tube which in general remains such during the life of the animal, and it must be viewed as the primative form of heart.

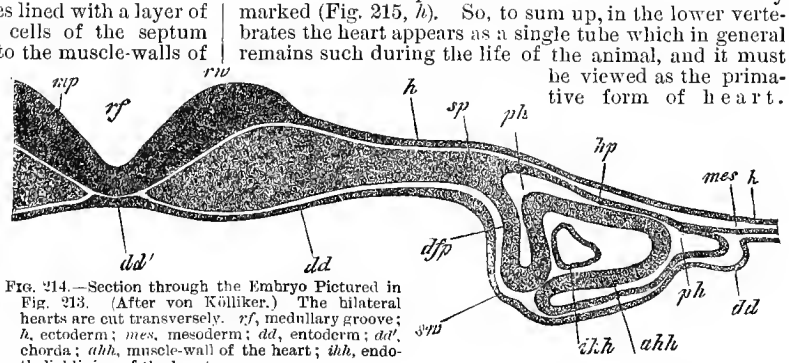

FIG. 214.—Section through the Embryo Pictured in Fig. 213. (After von Kölliker.) The bilateral hearts are cut transversely. *rf*, medullary groove; *h*, ectoderm; *mes*, mesoderm; *dd*, entoderm; *dd'*, chorda; *ahh*, muscle-wall of the heart; *ihh*, endothelial lining of the heart.

Higher up the scale the heart arises before the foregut is formed, from that portion of the splanchnopleur which later on lies in the median line of the embryo. It is this part which is to give rise to the heart, and in the higher

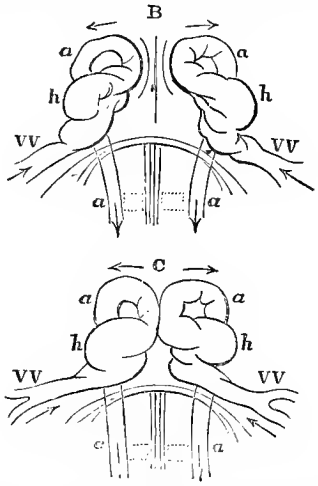

Fig. 215.—Sketches Showing the more Advanced Condition of the Bitubular Heart of the Rabbit. 22 times. (After Allen Thomson.) *C* is more advanced than *B*. *VV*, omphalo-mesenteric veins; *h*, heart; *a*, aorta; the arrows indicate the direction of the circulation.

animals the heart arises before the lateral parts have reached the median line (Hertwig). The two hearts then unite into a straight tube which is destined to become separated into the right and left hearts of the adult.

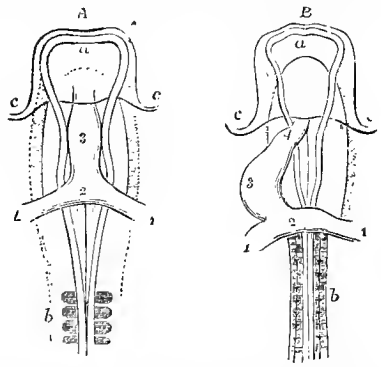

Fig. 216.—Outlines of the Anterior Half of the Chick Viewed from the Ventral Side, Showing the Heart in its Earlier Stages of Development. × 20 times. (From Qnain, after Remak.) *A*, thirty hours; *B*, forty hours; *a*, anterior cerebral vesicle; *b*, myotomes; *c*, cephalic fold; 1, omphalo-mesenteric veins; 2, 3, 4, the heart.

Fig. 216 is a ventral view of two chicks just after the two primary tubes of the heart have united. It is seen that the veins (1) enter from behind, but the relation is soon changed by the heart becoming bent as is already indicated in Fig. 218.

Fig. 217 shows the general form of the heart in a very young human embryo. The front of the thorax has been cut away, cutting also through the transverse septum and opening the body cavities. The entrance of the veins still lies behind, and the aorta in front, but the heart has already formed one complete loop, making of it an S. Fig. 218 is a profile of the same embryo, and the heart is indicated as a cast of its cavity. It shows the variations in calibre of the tube throughout its length. At a somewhat later stage the heart is bent upon itself more, and its walls have also become thickened. Figs. 219 and 220 are ventral and lateral views of a reconstruction at this stage. The profile view again gives a cast of the heart cavity, which now shows the beginning of the auricle

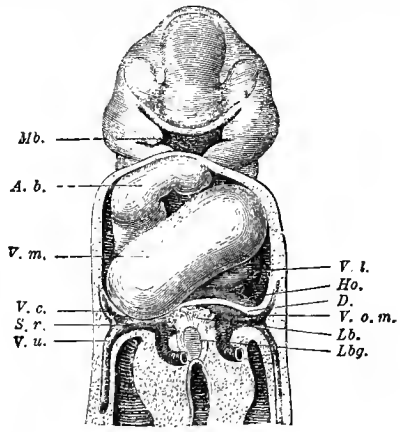

Fig. 217.

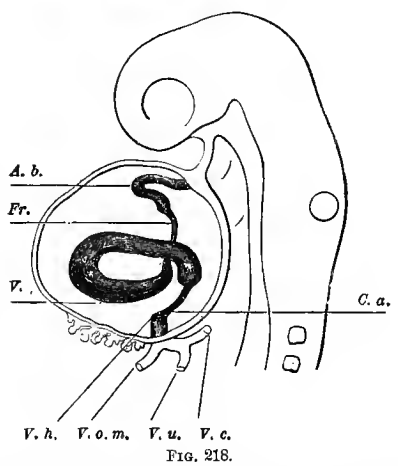

Fig. 218.

Figs. 217 and 218.—Ventral and Profile Reconstructions of His's Human Embryo, Lg. × 40 times. (After His.) In the profile view only the outline of the cavity of the heart is shown. *V.*, ventricle; *A. b.*, bulbus aortæ.

(*V.h.*) At this time the heart is partly tilted over and the veins enter on the dorsal side. Viewed from in front, the auricles, which are just appearing, cannot be seen because they now lie on the dorsal side. A stage later

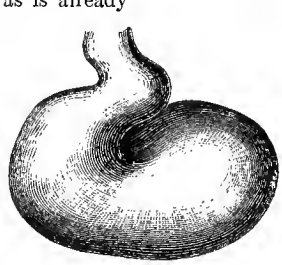

Fig. 219.

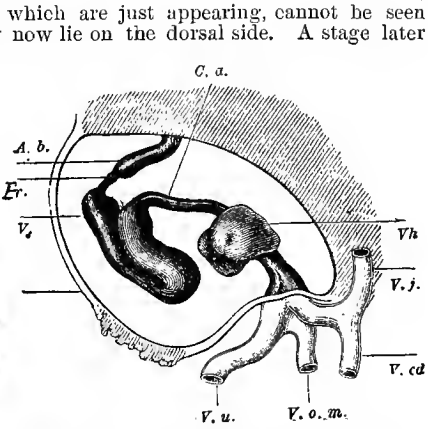

Fig. 220.

Figs. 219 and 220.—Ventral and Profile Reconstruction of His's Embryo, Lr. × 40 times. (After His.) *V*, ventricle; *Vh*, auricle; *A. b.*, bulbus aortæ.

(Figs. 221 and 222), the adult form can already be recognized. The heart has undergone a half revolution in addition to the S-formation. The veins enter nearer the head and the artery arises behind, or away from the head. The aorta lies upon the ventral side and the auricles clasp it from the dorsal. Fig. 222 shows the great irregularity of the cavity.

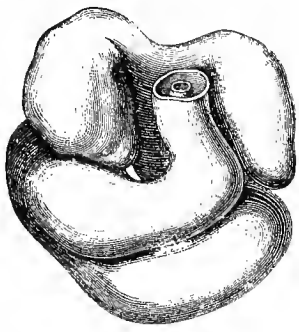

FIG. 221.

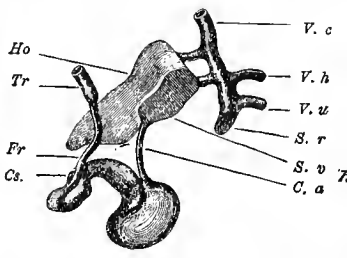

FIG. 222.

FIGS. 221 and 222.—Ventral and Profile Reconstruction of His's Embryo, Bl. × 40 times. *Ho*, auricle; *C.a*, auriculo-ventricular canal; *Tr*, aorta.

A profile view of a heart of this stage is shown in Fig. 223, which shows the relation of the heart to the surrounding organs. The auricle (*A*) is now in front and the ventricle (*V*) behind. The larger veins enter on the dorsal side by one common opening into the right side of the auricle, the future right auricle.

After the heart has once reached this stage it is only to be separated into its right and left tubes to produce the mammalian heart. In some of the lower animals this never takes place, and in others it is only partial. In

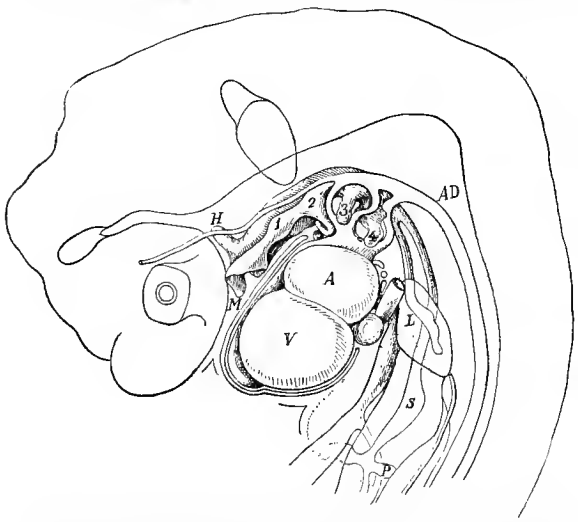

FIG. 223.—Reconstruction of a Human Embryo enlarged sixteen times, and viewed from the left side. *H*, hypophysis; 1, 2, 3, and 4, branchial pockets; *M*, mouth; *A*, auricle; *V*, ventricle; *AD*, descending aorta; *L*, lung; *S*, stomach; *P*, pancreas.

cases of arrested development the human heart in the adult may show any of its embryological forms, as, for instance, an open foramen ovale.

Figs. 224 and 225 show the interior of two stages of early human hearts, taken from models made by His. In Fig. 224, the auricle is quite enlarged and the vein enters on the right side. The ventricle is considerably smaller and its walls are much thicker than those of the auricle. This is usually the case with the hearts of embryos, as they die with the ventricles contracted and the auricles filled with blood. Between the two there is a narrowed auriculo-ventricular canal and with a corresponding constriction on the outside of the heart. Fig. 225 shows a more advanced stage. The general state of the heart is much as it is in the Fig. 224, only that the auricles are "shoved" into the ventricle. This is of considerable importance, as we shall later on see. In both cases the aorta arises from the right side of the ventricle, and in its further development one-half of it must be transferred to the left side in order to produce the aorta proper, while the half which remains becomes the pulmonary artery.

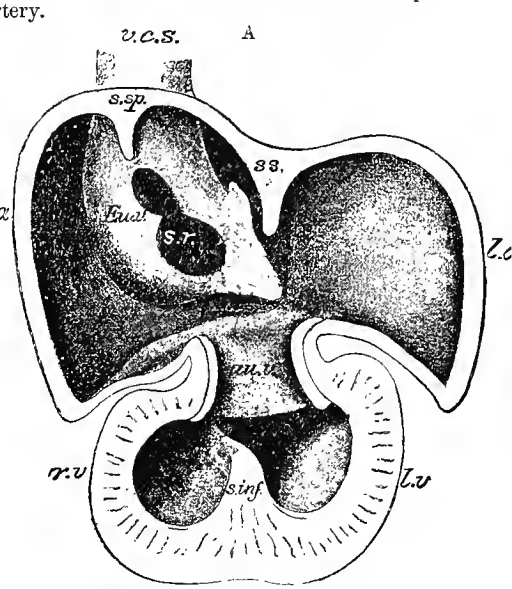

FIG. 224.

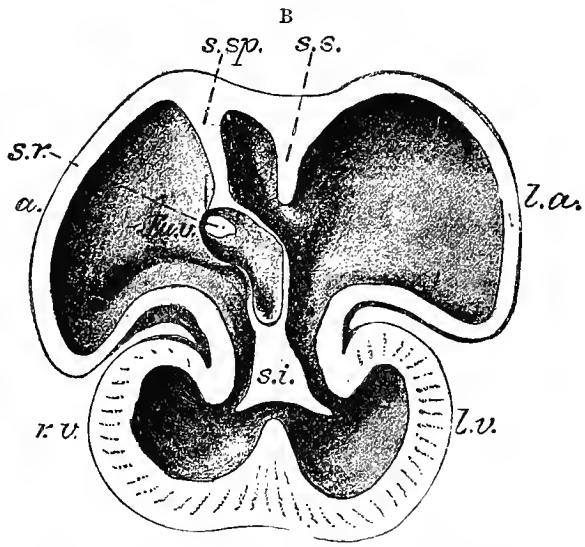

FIG. 225.

FIGS. 224 and 225.—Two Stages in the Formation of the Septum Intermedium in the Heart of the Human Embryo. (From Quain, after His.)
In *A* the septum is represented as growing from a triangular area to the left of the sino-auricular orifice; in *B* it has coalesced with the endocardial cushions, and lies like a stopper in the auricular canal.
r.a. and *l.a.*, right and left auricle; *r.v.* and *l.v.*, right and left ventricle; *s.r.*, sinus reuniens; *Eu.v.*, Eustachian valve: *s.sp.*, septum spurium; *s.s.*, septum superior; *s.inf.*, septum inferior; *s.i.*, septum intermedium; *v.c.s.*, vena cava superior dextra.

The first important change in the separation of the heart into its two lobes is the formation of two septa, one arising in the auricle, *S.s.*, which grows backward, and one in the ventricle, *S.inf.*, which grows forward. At the same time that these are growing toward each other, a cushion of connective tissue, *s.i.*, is formed upon the two lips of the slit-like auriculo-ventricular opening

which aids to complete the septum of the heart. This cushion, or septum intermedium, soon separates the auriculo-ventricular opening into two canals, the right and the left, to become the right and left auriculo-ventricular canals, respectively.

The septum of the auricle is completed by the septum superior growing backward to unite with the septum intermedium. Before this takes place, however, several changes take place in the septum (Figs. 226, 227, and 228).

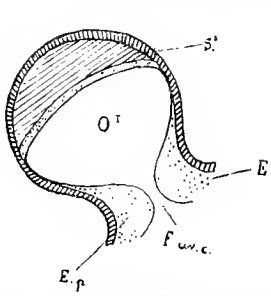

FIG. 226.

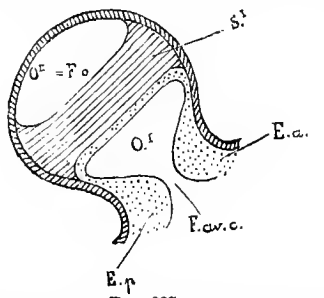

FIG. 227.

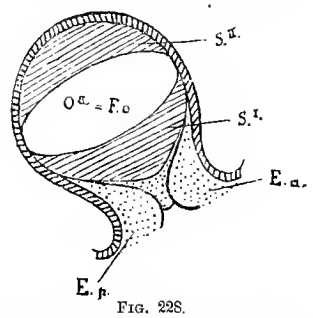

FIG. 228.

FIGS. 226, 227, and 228.—Side views of three stages, to show the formation of the foramen ovale. (After Born.) *S'*, first portion of the superior septum; *S''*, second portion of the superior septum; *O'*, first foramen ovale; *O''*, secondary opening or true foramen ovale; *E.p.*, endothelial cushion in the auriculo-ventricular opening.

These figures represent three stages of a lateral view of the two septa above named, with the opening between them. In Fig. 226, the septum superior is forming, but the *S.* intermedium is not yet complete. It was at first thought that the opening between them, *O'*, produced the foramen ovale, but later observations by Born showed that there is a secondary rupture in the septum superior which is destined to become the true foramen ovale (Fig. 227, *O''*). The portion of the septum superior which has been cut off by the formation of the foramen ovale, unites with the septum intermedium as shown in Fig. 227. The secondary septum, *S''*, later on forms the limbus of Vieussens, and the first, *S'*, the valve of the foramen ovale.

A partial septum of the heart is first met with in certain classes of ganoid fishes (Dipnoi), where it arises by a union of muscle-columns in the auricle. This is a very incomplete septum, which is gradually increased in the amphibia. In neither of these cases has the septum reached the auriculo-ventricular opening. This gives us the former it is multiple, and in the latter, as a rule, single. It is therefore seen that the formation of a secondary or true foramen ovale, as described by Born, is confirmed by the comparative anatomical evidence (see Born, *Arch. f. mik. Anat.*, Bd. 33, and Röse, *Morph. Jahrbuch*, Bd. 15 and 16).

The opening of the vein is guarded by two folds of the walls of the heart, which really form a complete bicuspid valve (Fig. 225). An additional fold extends to this from in front, the septum spurium, *S.sp.* Later on, the orifice enlarges to incorporate a portion of the veins into the auricle, but the right lip of the opening remains permanently as the Eustachian valve. The pulmonary veins are formed later. They grow from the lungs to the left auricle.

Returning to a stage of heart as represented in Fig. 225, we notice that the common ventricle shows a constriction on the outside which corresponds to a septum forming on the inside. As this septum from the inside, the septum inferius, grows toward the S. intermedium, it must also grow toward the aorta to join a septum aorticum which is forming there. Figs. 229–231, show how this is brought about. Fig. 229 represents a stage in which the auricles empty wholly on the left side and the aorta arises wholly on the right. As the inferior septum arises the auriculo-ventricular opening moves, as it were, toward the aorta; and when the septum inf. unites with the S. intermedium it cuts the auriculo-ventricular opening in such a manner, that the blood coming from the

an auricle partly divided, both compartments communicating with each other, and through a common opening with a single ventricle, much as is shown in the heart of the human embryo pictured in Fig. 224. In the reptiles the septum is complete, and we have two distinct auricles communicating independently with the ventricle. We can view this as the completion of the second stage, *i.e.*, a complete union of the septum superior and the septum intermedium. In birds and mammals, however, there is a secondary rupture of the septum of the auricle; in right auricle passes to the right ventricle, and the blood from the left auricle to the left ventricle. A small opening exists for quite a while between the two ventricles, but, later on, this is closed by a membrane of connective tissue. Before the ventricles are completely separated from each other, a view of the septum appears much as is shown in Fig. 232. The aorta is already completely separated into two vessels: the one which communicates with the right ventricle, communicating above with the fifth aortic arch, and the one from the left with the

fourth. The fourth is destined to become the aorta, and the fifth the ductus arteriosus from which the pulmonary artery arises.

At an early stage the tissue of the ventricle walls becomes spongy on the inside. These meshes and columns play a very important part in the formation of the valves,

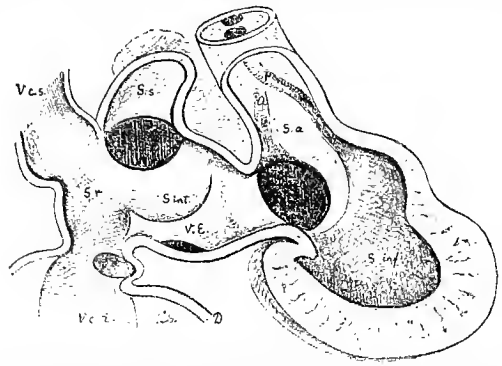

FIG. 232.—Opened Heart of a Human Embryo Seen in Profile. × 33 times. musele-columns, and the tendons to the valves. We have seen that the septum intermedium is formed in the auriculo-ventricular canal and divides it into a right and a left half. When this is complete a section of the heart gives a picture as shown in Fig. 233. At the same time

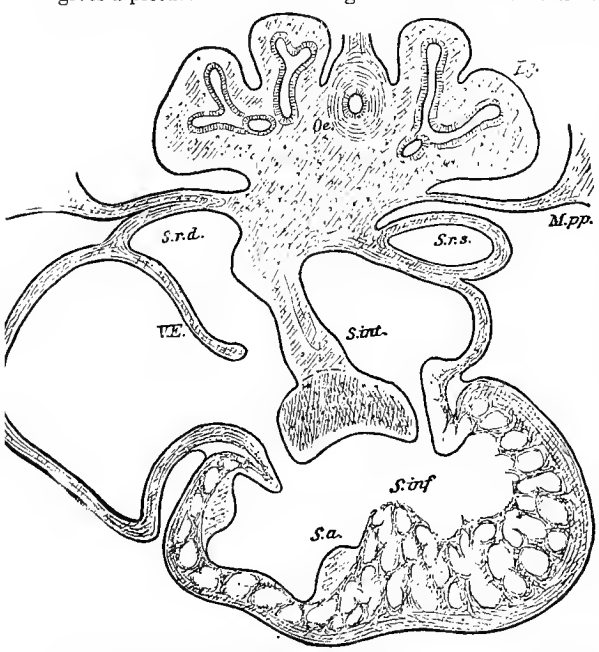

FIG. 233.—Section through the Heart of a Human Embryo to Show the Formation of the Columnæ Carneæ. × 36 times. (After His.) *Oe.*, œsophagus; *Lg.*, lung; *M.pp.*, membrana pleuro-pericardiaca; *S.r.d.* and *S.r.s.*, right and left horns of the sinus reuniens; *V.E.*, Eustachian valve; *S.int.*, septum intermedium; *S.inf.*, septum inferior; *S.a.*, septum aorticum.

a portion of the auricle is, as it were, pushed into the ventricle, as the figure shows. This invagination takes with it a portion of the epicardium, to be incorporated in the formation of the valve. Connective tissue is incorporated in the formation of the valve at its beginning, although the great bulk of the valve is at this time composed of muscular fibres. The burrowing of the ventricle walls includes also the valves, and in this way, as the figure indicates, the primitive chordæ tendineæ are formed. Soon, however, the bands lose their muscle-fibres, in the portions which form the chordæ, and in other portions, farther away from the valve, the muscle-fibres increase to form the papillary muscle. The valves have therefore a double origin: (1) Peripheral, and (2) from the septum intermedium. According to His, the tendons attached to the valves arising from the periphery, have their permanent attachment to the valve from the beginning, while a portion of those passing to the valve and arising from the septum intermedium may possibly shift their valvular attachment.

The muscle-walls of the two ventricles are at first of the same thickness, but later on that of the left becomes heavier than that of the right. The spongy layer in the ventricle is covered with endocardium, and from this layer the columnæ carneæ arise.

Distinct muscle-tissue is not present until the heart is quite well formed, although it begins to beat long before this. The nerves grow into the heart from the spinal ganglia, at a much later period, as shown by Onody and by W. His, Jr. *Franklin P. Mall.*

HEREDITY. The progress of our knowledge in pathology and etiology constrains me to curtail the boundary of hereditary diseases since the former article under the above title was written. I am now satisfied that leprosy should be dropped from the list, and that heredity figures little in tuberculosis. Bacteriology has made good its claim on both diseases, and both are found to be transmissible in direct ratio with facilities for communication in the recognized habit of contagious maladies. The bacilli of the two diseases are strikingly similar, both morphologically and in tardiness of growth and multiplication.

Leprosy is never congenital and is never developed until months, and sometimes years, after contagion has had time to do its work. It is most prevalent among people whose habits of life bring them into closest social relations, and segregation of those affected is the most effectual mode of checking its spread. There is even less difficulty in tracing the probable or possible source of contagion than exists in the case of searlatina and measles, though it is vastly less communicable.

Congenital tuberculosis has been found in a very few instances within the last five years, and congenital pneumonia has been reported in at least one instance. The bacillus tuberculosis is sometimes found in the blood, associated with diffused miliary tuberculosis as causative of the latter. It is conceivable that a woman affected with this form of the malady might communicate it to her unborn child through the placenta; but it is not in accordance with the accepted etiology and known progress of tuberculosis, to presume that its bacilli, taken into the blood of a fœtus, may remain latent, with or without reproduction, and the usual local effects be postponed for many years. It is quite reasonable that the opportunities for infection afforded by the close social relations of kindred dwelling together have been mistaken for heredity in this disease, as in leprosy. On the other hand, we have the experiment of Sanchez-Toledo, of Paris, who has injected pure cultures of Koch's bacillus tuberculosis into the jugular vein of pregnant guinea-pigs, but failed to find the bacilli in the blood or organs of the progeny, though the mothers became tuberculous.

Uncured syphilis in either parent at time of procreation, or during gestation in the mother, is quite apt to be transmitted to the fœtus, but may be controlled by active treatment of the mother before parturition. Thorough eradication of the syphilitic virus by prolonged treatment terminates its transmissibility.

As to gout, rheumatism, goître tending to cretinism, scrofula, cancer, and the various neuroses, heredity figures as a predisposing factor in some obscure way. In the case of tuberculosis, predisposition probably means unusual susceptibility to the admission or action of the bacilli; perhaps extraordinary delicacy of epithelium in the respiratory or intestinal tract, which may be inherited. We might even suppose a duplex inherited predisposition to syphilis, consisting in a delicate epithelium associated

with a propensity for promiscuous sexual indulgence. Whether such conjunction be most apt to occur in the sanguine temperament, is a point for investigation by the numerical method. *S. S. Herrick.*

HEREDITY IN THE OVUM AND SPERMATOZOÖN.[1]

The purpose of this article is to give a summary of recent researches upon the structure and relations of the male and female germ-cells in connection with the phenomena of reproduction and heredity.

Much progress has been made of late years in the knowledge of the stages through which the ovum and spermatozoon pass before and after union, and in the abnormal effects produced by experimental, chemical, and mechanical disturbances. The latter bear directly upon teratology. Speculation and investigation upon heredity have kept pace with embryological research, and at the present time the marvellous transformation of an infinitesimal speck of protoplasm (the fertilized ovum) into the adult body with its hereditary structure and tendencies, is under the focus of researches in the following branches of biological science:

A. DEVELOPMENT OF THE RACE.—*Heredity.*—1. *Speculative*, including theories of *Pangenesis* and *Continuity of Germ-plasm*, Darwin, Weismann, etc.

2. *Anthropological*, including data from human anatomy and anthropology, teratology, etc.

3. *Comparative*, including data from the evolution of lower types of animals (palæontology).

4. *Experimental* (or experimental evolution), including influences upon offspring of experiments upon the structure, function, or environment of parents. Systematic researches in this line have just begun.

B. DEVELOPMENT OF THE INDIVIDUAL.—*Embryology.* 5. *Normal*, including the phenomena of ovogenesis and spermatogenesis, fertilization, histogenesis, intercellular action, as derived from study of lower types of animals and plants.

6. *Experimental*, the diversion of normal phenomena by mechanical, chemical, and thermal experiments upon different stages of development.

It will be seen that the two objects of investigation are

The Body-cells, or Soma, = the expression of Heredity.

The Germ-cells = the potential vehicles of Heredity.

The many problems resolve themselves into the simple questions:

How do the parent germ-cells transform into the offspring body, and how does the latter influence the new germ-cells, or, what are the total relations between the body-cells and germ-cells?

A. DEVELOPMENT OF THE RACE.—1. *Speculative Heredity.*—In a valuable summary of the past theories of heredity [2] J. A. Thomson distinguishes three general problems, which are often confused. 1st. What characters distinguish the germ-cells from other cells of the body? 2d. How do the germ-cells derive these distinguishing characters? 3d. How shall we interpret "particulate" inheritance, or the reappearance of single peculiarities in the offspring?

The various theories may be grouped under two heads, "Pangenesis of Germ-cells" and "Continuity of Germ-cells," according to the dominating idea in each.

a. Pangenesis.—The idea pervading pangenesis was first expressed by Democritus that the "seed" of animals was derived by contributions of material particles from all parts of the bodies of both sexes, and that like parts produced like. Two thousand years later, Buffon revived this conception of heredity in his "molecules organiques." In 1864 Herbert Spencer suggested the existence of "physiological units," derived from the body-cells of the parent, forming the germ-cells and then developing into the body-cells of the offspring. This theory is designed to explain how changes in the body-cells of the parent can be transmitted to the offspring. ("Use-inheritance, or "inheritance of acquired characters").

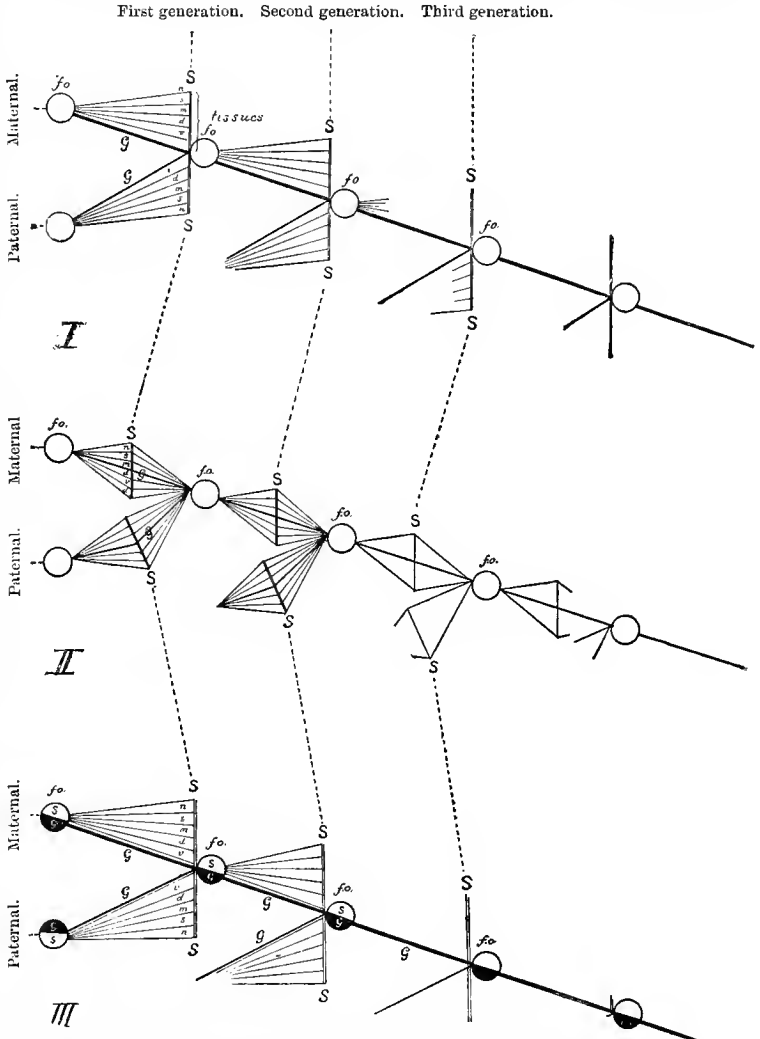

FIG. 234.—Illustrating, I. Normal Histogenesis; II. Theory of Pangenesis; III. Theory of Continuity of Germ-plasm. The fertilized ovum (*f.o.*) contains the maternal and paternal characteristics. This expands into the adult body, or Soma (*S*), composed of *somatic cells* (*n*, *s*, *m*, *d*, *r*) constituting the nervous, secretory, muscular, digestive, and other tissues, besides the *germ-cells* (*G*) of the reproductive organs. I. Histogenesis.—Showing the successive rise, *G*, and union, *f.o.*, of the maternal and paternal germ-cells by direct histogenesis. II. Pangenesis.—Showing the tissues of the body *S*, contributing to the germ-cells *G*, so that each *f.o.* is composed of elements (gemmules) from both the somatic and germ-cells. III. Continuity of the Germ-plasm.—Showing the division of the embryo, *f.o.*, into somatoplasm, *s* (from which arise the body-cells), and germ-plasm, *G* (which passes direct to the germ-cells), establishing a direct continuity.

It is interesting to note the course of Darwin's thought upon this matter in his published works and in his "Life and Letters." He was at first strongly opposed to the views advanced by Buffon, by Erasmus Darwin, and ex-

panded by Lamarck, that changes in the parents are transmitted to offspring, as the main cause of evolution. But gradually becoming convinced that his own theory of natural selection could not account for all the facts of evolution, he unconsciously became a strong advocate of Lamarck's theory and contributed to it a feature which Lamarck had entirely omitted, namely, a theory of heredity expressly designed to explain the transmission of aequired characters. Darwin's "provisional hypothesis of pangenesis"[3] postulated a material connection between the body-cells and germ-cells by the circulation of minute buds from each cell; each body-cell throws off a "gemmule" containing its characteristics; these gemmules multiply and become especially concentrated in the germ-cells; in the latter they unite with others like themselves; in course of development they grow into cells like those from which they were originally given off (see Fig. 234).

Galton,[4] who has always been doubtful in regard to use-inheritance, while advancing a theory of "continuity," partly approved Darwin's pangenesis idea in the cautious statement: "Each cell may throw off a few germs that find their way into the circulation and thereby have a chance of entering the germ-cells." At the same time Galton contributed very important experimental disproof of the existence of "gemmules," and, in fact, of the popular idea of the circulation of hereditary characters in the blood, by a series of carefnl experiments upon the transfusion of blood in rabbits; he found that transfused blood did not convey with it even the slightest tendency to transfer normal characteristics from one variety of rabbit to another.

Professor Brooks,[5] of the Johns Hopkins University, then contributed an original modification of pangenesis in which the functions of the ova and spermatozoa were sharply differentiated. (1) He regarded the ovum as a cell especially designed as a storehouse of hereditary characteristics, each characteristic being represented by material particles of some kind; thus hereditary characters were handed down by simple cell division, each fertilized ovum giving rise to the body-cells in which its hereditary characters were manifested, and to new ova in which these characters were conserved for the next generation (this portion of Brooks's theory is very similar to Galton's and Weismann's). (2) The body-cells have the power of throwing off "gemmules," but this is exercised mainly or exclusively when its normal functions are disturbed, as in metatrophic exercise or under change of environment. (3) These gemmules may enter the ovum, but the spermatozoön is their main centre. According to this view the female cell is rather conservative and the male cell progressive; the union of these cells produces variability in the offspring, exhibited especially in regions of the offspring corresponding to the regions of functional disturbance in the parent. This hypothesis was well considered, and while that feature of it which distinguishes the male and female germ-cells as different in kind has been disproved, and the whole conception of gemmules is now abandoned, the fact still remains that we shall nevertheless be obliged to offer some hypothesis to explain the facts disregarded by Weismann for which Brooks provides in his theory of the causes of variation.

b. Continuity of Germ-cells.—The central idea here is an outgrowth of our more moderu knowledge of embryogenesis and histogenesis, and is, therefore, comparatively recent; it is that of a fundamental distinction between the "germ-cells," as continuous and belonging to the race, and the "body-cells," as belonging to the individual. Weismann has refined and elaborated this idea, bnt it was not original with him.

Richard Owen,[6] in 1849, Haeckel,[7] in 1866, Rauber,[8] in 1879, in turn, dwelt upon the distinction which Dr. Jaeger, now of manufacturing fame, first clearly stated:

"Through a great series of generations the germinal protoplasm retains its specific properties, dividing in every reproduction into an ontogenetic portion, ont of which the individual is built up, and a phylogenetic portion, which is reserved to form the reproductive material of the mature offspring. This reservation of the phylogenetic material I described as the continuity of the germ protoplasm. . . . Encapsuled in the ontogenetic material the phylogenetic protoplasm is sheltered from external influences, and retains its specific and embryonic characters." The latter idea has, under Weismann, been expanded into the theory of isolation of the germ-cells.

Galton introduced the term "stirp" to express the sum total of hereditary organic units contained in the fertilized ovnm. His conception of heredity was derived from the study of man, and he supported the idea of continuity in the germ-cells in order to account for the law of transmission of "latent" characters; it is evident from this law that only a part of the organic units of the "stirp" become "patent" in the individual body; some are retained latent in the germ-cells, and become patent only in the next or some succeeding generation. For example, the genius for natural science was "patent" in Erasmus Darwin, grandfather of the great naturalist, it was "latent" in his son, and reappeared intensified in his grandson, Charles Darwin.

Weismann has carried the hypothesis of continuity to its extreme in his simple and beautiful theory of heredity, which is fonnded upon the postulate *that there is a distinct form of protoplasm, with definite chemical and molecular properties, set apart as the vehicle of inheritance; this is the germ-plasm, G, quite separate from the protoplasm of the body-cells or somatoplasm, S.* Congenital characters arise in the germ-cells and are therefore *blastogenetic*, while acqnired characters arise in the body-cells and may be called *somatogenetic*.

To clearly understand Weismann's hypothesis, let us follow his history of the fertilized ovum in the formation of the embryo. It first divides into *somatoplasm* and *germ-plasm* (see Figure 234, III.); the somatoplasm supplies all the tissues of the body—*n*, *s*, *m*, *d*, *v*, nervous, muscular, vascular, digestive, etc.—with their quota of hereditary structure: the germ-plasm is kept distinct, throughout this early process of embryonic cell-division, until it enters into the formation of the nuclei of the new reproductive cells, the ova or spermatozoa of the next generation. Here it is isolated from the changes of function in the somatoplasm, and in common with all other protoplasm is capable of unlimited growth by cell-division without loss or deterioration of its past store of hereditary properties; these properties are lodged in the nucleus of each ovum and spermatozoön, and these two cells, although widely different in external accessory structure (because they have to play an active and passive part in the act of conjugation), are exactly the same in their essential molecular structure, and the ancestral characters they convey differ only because they come along two different lines of descent. When these cells unite they carry the germ-plasm into the body of another individual. Thus, while the somatoplasm of each individual dies, the germ-plasm is immortal and simply shifts its abode from one generation to another; it constitutes the chain from which the individuals are mere offshoots. Thus the germ-plasm of man is continuous with that of all ancestors in his line of descent, and we have an explanation of the early stages observed in development in which the human embryo passes through a succession of metamorphoses resembling the adult forms of lower types of animals (Von Baer's law).

In order to emphasize, as it were, the passage of the germ-plasm from one generation to another without deterioration in its marvellous hereditary powers, Weismann added the idea of its *physiological isolation*. Not only does he repudiate the pangenesis notion of increment of germ-plasm by addition of gemmules, but he believes that it is unaffected by any of the normal changes in the somatic or body-cells. As this continuity and isolation would render impossible the transmission of characters acquired by the somatoplasm, Weismann began to examine the evidence for such transmission, and coming to the conclusion that it was insufficient, in his notable essay on "Heredity," in 1883, he boldly attacked the whole Lamarckian theory, and has continued to do so in all his subsequent essays.

Being forced to explain evolution without this factor, he claimed that variation in the germ-plasm was constantly arising by the union of plasmata from different lines of ancestral descent which occurs in fertilization, and that these variations are constantly being acted upon by Natural Selection to produce new types. He thus revived Darwin's earlier views of evolution, and this in part explains his strong support by English naturalists.

Weismann admits the general principle of *ovum sanum in corpore sano*, but denies that any local specific disorders or changes in the parent body *which are not congenital* (*i.e.*, in the parental germ-plasm) ever result in similar specific localized disorders or changes in the offspring body. The mutilation of a parent will not reappear in the loss or abnormal development of the same structure in the child. The effects of use and disuse are not inherited. In these opinions of Weismann, Kölliker, His, Pflüger, Ziegler, and other eminent anatomists and physiologists concur.

Speculative Heredity has not yet produced a satisfactory theory of hereditary transmission. Weismann's "germ-plasm," as a distinct substance, is disproved by recent embryology—there is no such continuous and specific form of protoplasm confined to certain cells. (See Histogenesis.)

We conclude this section by a brief statement of what is required in a complete working theory of heredity. The matter of first importance in life is *the repetition and preservation of type*, the principle which insures the unerring accuracy and precision with which complex organs are built up from the germ-cells; the force of regression and the more remote forces of reversion all work in this conservative direction.

The matter of second importance, but equally vital to the preservation of races, in the long run, is *the formation of new types* adapted to new circumstances of life.

In the following table are placed some of the facts of human evolution, and as they are part of inheritance, they also constitute the main external phenomena of heredity

PHENOMENA OF HEREDITY.

Conservative (toward past type).	*Neutral.*	*Progressive* (toward future type).
a. Repetition of parental type.	Fortuitous and	*a.* Definite Variation in single characters, by accumulation =:
b. Regression (in many characters) to contemporary race type.	Indefinite	*b.* Definite Variation in many characters (from contemporary race type).
c. Reversion (mainly in single characters) to past race type.	Variability.	

2 and 3. *Anthropological and Comparative Heredity.*—The bearing of these branches of study upon heredity is as follows: Is there any proof that definite changes in the body, whether due to physiological and anatomical effects of certain trades or occupations, or to accidents, or to pathological changes, produce corresponding changes in the ova and spermatozoa, so as to reappear in offspring. The supposed influences of certain occupations has, for example, been discussed by Arbuthnot Lane, in a series of papers in the *Journal of Anatomy and Physiology*; he maintains the theory of inheritance of functionally produced modifications.

If such inheritance does take place there must be some interchange of material (as implied by *Pangenesis*) or of forces between the parent body and the reproductive cells.

a. Physiological Data.—There are three phenomena about which there is much scepticism, to say the least, which bear upon the question of *a possible interchange of forces between the body and the germ-cells.* These are the inheritance of mutilations, the influence of previous fertilization, and the influence of maternal impressions. They are all in the quasi-scientific realm, which embraces such mental phenomena as telepathy. That is, we incline to deny them simply because we cannot explain them.

a. Mutilations.—Since the publication of Weismann's essays the subject of inherited mutilations has attracted renewed interest. I would first call attention to the fact that this matter has only an indirect bearing, for a mutilation is something impressed upon the organism from without; it is not truly "acquired;" the loss of a part by accident produces a sudden but a less profound internal modification of the organism than the loss of a part by degeneration. Most of the results are negative; many of the so-called "certain" cases prove upon investigation to be mere coincidences. Weismann[9] himself experimented upon white mice, and showed that nine hundred and one young were produced by five generations of artifically mutilated parents, and yet there was not a single example of a rudimentary tail or of any other abnormality in this organ. The cases of cleft ear-lobule have recently been summed up.[10] Israel reports two cases of clefts in which the parents' ears were normal. Schmidt and Ornstein report affirmative cases. His shows that an affirmative case, cited by V. Zwiecki, is merely an inherited peculiarity. The entire evidence is unsatisfactory, and, upon the whole, is decidedly negative.

Not so, however, in cases where the mutilation results in a general disturbance of the normal functions of different organs, as in the experiments conducted by Brown-Séquard[11] upon guinea-pigs, in which we see "acquired variation" intensified. In these, abnormal degeneration of the toes, muscular atrophy of the thigh, epilepsy, exophthalmia, etc., appeared in the descendants of animals in which the spinal cord or sciatic nerve had been severed, or portions of the brain removed. It was also shown that the female is more apt to transmit morbid states than the male; that the inheritance of these injuries may pass over one generation and reappear in the second; that the transmission by heredity of these pathological results may continue for five or six generations, when the normal structure of the organ reappears. These cases, which are incontestable, at first sight appear to establish firmly the transmission of acquired characters; they were so regarded by Brown-Séquard. These lesions act directly upon the organs, and the abnormal growth in these organs appears to be transmitted. But can they not be interpreted in another way, namely, that the pathological condition of the nerve-centres has induced a direct disturbance in those portions of the germ-cells which represent and will develop into the corresponding organs of the future offspring?

b. Previous Fertilization.—Consider next the influence exerted upon the female germ-cell by the mere proximity of the male germ-cell, as exhibited in the transmission of the characteristics of one sire to the offspring of a succeeding sire, observed in animals, including the human species, also in plants. The best example is the oft-quoted case of Lord Morton's mare, which reproduced in the foal of a pure Arab sire the zebra markings of a previous quagga sire.

Some physiologists have attempted to account for these remarkable indirect results from previous fertilization or impregnation, by the imagination of the mother having been strongly affected, or from interchange between the freely inter-communicating circulation of the embryo and mother, but the analogy from the action in plants (in which there is no gestation but early detachment and development of the fertilized cells) strongly supports the belief that the proximity of male germ-cells acts directly upon the female cells in the ovary. All that we can deduce from these facts is that in some manner the normal characteristics and tendencies of the ova are modified by the foreign male germ-cells without either contact or fertilization.

c. Maternal Impression.—The influence of maternal impressions in the causation of definite anomalies in the fœtus is largely a matter of individual opinion.

It is denied by some high authorities, led by Bergmann and Leuckart. Many medical practitioners, however, believe in it, and I need hardly add that it is a very general popular belief, supported by numerous cases. The bearing which this mooted problem has upon the discussion is this: if a deviation in the development of a child is produced by maternal impression, we have a proof that deviation from normal hereditary tendencies can be pro-

duced without either direct vascular or nervous continuity.

We see that there exists an analogy between the experiments of Brown-Séquard and Obersteiner, the influence of the previous sire and the influence of maternal impressions. These three classes of phenomena all tend to show that the hereditary forces which normally reproduce organs in their typical and perfect form may be checked or diverted by other forces which exert a profound abnormal influence upon the body, chiefly through the nervous system. This diversion of the normal direction of heredity, in the opinion of the writer, compels us to assume that there is some functional and structural connection between the body-cells and the germ-cells, the nature of which is at present wholly unknown. Our ignorance as to the nature of this connection between the body-cells and germ-cells does not compel us to deny that it exists. To discover this link is now one of the chief ends of biology.

β. *Morphological Data.*—We must keep in mind that the body-cells (somatoplasm) and germ-cells (germ-plasm) were originally one, as in all single-celled organisms like the amœba. In course of evolution the separation of these two kinds of cells proceeded gradually, and *comparative heredity* shows that the power of reproduction may not be confined to the germ-cells but may extend in a feebler degree into the body-cells as well.

a. The *separation of the germ-cells* is in the regular order of evolution upon the principles of physiological division of labor. The unicellular organisms combine all the functions of life in a single mass of protoplasm, that is, in one cell. In the rise of the multicellular organisms the various functions are distributed into groups of cells, which specialize in the perfecting of a single function. Thus the reproductive cells should fall into the natural order of histogenesis, and the theory of their entire separation is more consistent with the laws governing the other tissues than the theory which we find ourselves obliged to adopt, that while separate they are still united by some unknown threads with the other cells. (Fig. 234, *I.*)

The structural separation of what we may call the race-protoplasm becomes more and more sharply defined in the ascending scale of organisms. Weismann's contention as to the absolutely distinct specific nature of the germ-plasm and somatoplasm has, however, to meet the apparently insuperable difficulty that in many multicellular organisms, even of a high order, the potential capacity of repeating complex hereditary characters, and even of producing perfect germ-cells, is widely distributed through the tissues.

For example, cuttings from the leaves of the well-known hot-house plant, *Begonia*, or portions of the stems of the common willow-tree, are capable of reproducing complete new individuals. This would indicate either that portions of the germ-plasm are distributed through the tissues of these organisms, or that each body-cell has retained its potential quota of hereditary characters. Among the lower animals we find the same power; if we cut a hydra or bell-animalcule into a dozen pieces, each may reproduce a perfect new individual. As we ascend in the animal scale the power is confined to the reproduction of a lost part in the process known as recrescence. As we well know, in the group to which the frog and salamander belong, a limb or tail, or even a lower jaw, may be reproduced. The only logical interpretation of these phenomena is, that the hereditary powers are distributed in the entire protoplasm of the organism, and the capacity of reproduction is not exhausted in the original formation of the limb, but is capable of being repeated.

There has been considerable discussion of late as to the seat of this power of *recrescence*. It seems not impossible that, in the vertebrates, it may be stored in the germ-cells, and it would be very interesting to ascertain experimentally whether removal of these cells would in any way limit or affect this power; we know that such removal in castration or ovariotomy sometimes profoundly modifies the entire nature of the organism, causing male characters to appear in the female, and female characters to develop in the male.

So far as man is concerned it has been claimed by surgeons that genuine recrescence sometimes occurs; for example, that a new head is formed upon the femur after exsection; Dr. V. P. Gibney informs the writer that this is an exaggeration, that there is no tendency to reproduce a true head, but that a pseudo-head is formed, which may be explained upon the principle of regeneration and individual transformism by use of the limb.

Pflüger's opinion is that recrescence does not indicate a storage of hereditary power, that there is no pre-existing germ of the member, but that the re-growth is due to the organizing and distributing power of the cells at the exposed surface, so that, as new formative matter arrives, it is built up gradually into the limb. This view would reduce recrescence to the level of the *regeneration* process which unites two cut sections of the elements of a limb in their former order. It is partly opposed to the facts above referred to, which seem to prove the distribution of the hereditary power. Yet it seems quite consistent to consider these three processes—*a*, reproduction of a new individual from every part; *b*, recrescence of a new member from any part; *c*, regeneration of lost tissues—as three steps indicating *the gradual, but not entire withdrawal of the reproductive power from the body-cells into the germ-cells.*

Among the reasons for believing in the complete separation of the germ-cells in man are the following: The very early differentiation of these cells in the embryo, observed with a few exceptions in all the lower orders of animals, and advancing so rapidly in the human female that several months before birth the number of primordial ova is estimated at seventy thousand, and is not believed to be increased after the age of two and a half years. The most patent practical proof is that we may remove every portion of the body which is not essential to life and yet the power of complete reproduction of a new individual from the germ-cells is unimpaired. Among the many reasons advanced for pensioning the crippled soldiers of our late war we never hear it urged that their children are incapacitated by inheritance of injuries. The strongest proof, however, rests in the evidence which may be cited from heredity of the extraordinary stability of the germ-cells which is the safeguard of the race.

b. The *specific nature of the germ-plasm* must be considered before we consider its relations. Wherein lies the conservative power of the germ-plasm, and in what direction shall we look for its transforming forces? You see at once that marvellous as is the growth of cells in other tissues, the growth of the germ-cell is still more so.

We find it utterly impossible to form any conception of the contents of the microcosmic nucleus of the human fertilized ovum, which is less than $\frac{1}{25}\frac{1}{0}\frac{1}{0}$ of an inch in diameter, but which is, nevertheless, capable of producing hundreds of thousands of cells like itself, as well as all the unlike cells of the adult organism. We can only translate our ideas as to the possible contents of this nucleus in the terms of chemistry and physics.[1]

According to the general law the germ-cell is considered as matter potentially alive and having within itself the tendency to assume a definite living form in course of individual development. The nucleus must be extraordinarily complex, for it contains within itself not only the tendencies of the present type, but of past types far distant. The supposition of a vast number of germs of structure is required by the phenomena of heredity: Nägeli has demonstrated that even in so minute a space as $\frac{1}{1}\frac{1}{0}\frac{1}{0}\frac{1}{0}$ cub. millimetre, 400,000,000 micellæ must be present.

Speculation has also been active in this field. Spencer[2] assumed an order of molecules or units of protoplasm lower in degree than the visible cell-units, to the internal or polar forces of which, and their modification by external agencies and interaction, he ascribed the ultimate responsibility in reproduction, heredity, and adaptation. This idea of biological units seems to the writer an essential part of any theory; it is embodied in Darwin's "gemmules," in Haeckel's "plastidules," yet, as Lankes-

ter says, the rapid accumulation of bulk is a theoretical difficulty in the material conception of units. In the direction of establishing some analogy between the repetition power of heredity and other better-known functions of protoplasm, Haeckel and Hering have likened heredity to memory, and advanced the hypothesis of persistence of certain undulatory movements; the undulations being susceptible of change and therefore of producing variability, while their tendency to persist in their established harmony is the basis of heredity. Bertbold, Gautier, and Geddes[13] have speculated in the elaboration of the idea of metabolism; the former holding the view that "inheritance is possible only upon the basis of the fundamental fact that in the chemical processes of the organism the same substances and mixtures of substances are reproduced in quantity and quality with regular periodicity."

We have merely touched upon these speculations to show that the unknown factors in heredity are also the unknown factors in operation in living matter. All we can study is the external form, and conjecture that this form represents matter arranged in a certain way by forces peculiar to the organism. These forces are exhibited or patent in the somatic cells; they are potential or latent in the germ-cells.

4. *Experimental Heredity.*—We must refer here again to the experiments of Brown-Séquard and of Obersteiner upon guinea-pigs, and to work which is now being instituted in France, and to some extent in England and Germany. This promises to be a most fruitful field of research by which the truth or falsity of Weismann's theory of heredity will be finally established.

Experimental evolution or heredity seeks to determine chiefly whether modifications produced in the parent, or a series of parents, are transmitted to offspring. To test the supposed inheritance of mutilations, Weismann has cut the tails off nine successive generations of mice without producing the slightest diminution of the tail in later generations. It will be possible to test the problem of maternal impressions, and the firmly established belief of breeders, that an ill-bred sire injures all the subsequent offspring of well-bred sires. Thus far no absolutely satisfactory results of this kind of experimental work have been recorded.

B. The Development of the Individual. — 5. *Normal Embryology.*—The structure and physiology of the germ-cells will ultimately yield the *physical* basis of the science of heredity. After all, the data which may be gathered from the four branches of heredity above considered are only indirect, the direct data must come from embryology. In the actual material and dynamics of the germ-cells and their relation to body dynamics we look for the physical basis of the following phenomena: *a*, Repetition of parental characters; *b*, variations from parental characters; *c*, reversion to ancestral characters; *d*, prepotency of one sex over the other; *e*, causes of determination of sex; *f*, causes of anomalies, monstrosities, abnormal births, multiple births. Some of these latter phenomena (*e*, *f*,) occur in course of development of the embryo; others can be traced directly back to the germ-cells in their earliest stages.

The Sexes.—We have naturally come to look upon the two sexes as fundamentally distinct. As regards heredity and our present study, they are fundamentally similar. Unlike as the male and female, the ovum and spermatozoon, are in external appearance, all the material and mechanism of inheritance is exactly the same in each. Sex is a secondary distinction, both in evolution and in the development of the individual.

The causes finally determining sex may come surprisingly late in development, and, according to the investigations of Düsing, and the experiments of Yung and of Giron,[15] are directly related to nutrition. High feeding favors an increase of the percentage of females, while, conversely, low feeding increases the males. In Yung's experiments with tadpoles the following results were obtained:

	Females.	Males.
Normal percentage	57	43
High nutrition	92	8

Geddes expresses this principle in physiological terms of metabolism, that anabolic (constructive) conditions produce females, while katabolic (destructive) conditions produce males.

I think we may now safely eliminate the factor of sex from our calculations upon the problem of heredity, and thus rid ourselves of one of the oldest and most widespread fallacies. We shall thus, in using the terms "paternal" and "maternal," imply merely the distinction between the qualities of two lines of ancestral descent.

Asexual Conjugation. — Let us, therefore, first consider Reproduction (Conjugation and Development) in those lower single-celled organisms in which there is no sex—such as the *Amœba*, or the somewhat higher types of Ciliated Infusoria. Of the forms described below, *Stylonichia* is an animalcule varying in diameter from one-eleventh to one-third millimetre; it is free, swimming in stagnant water, or it sometimes creeps on the surface of plants. *Glaucoma* is also found in ponds, and swims by means of five cilia upon its ventral surface.

Maupas on Conjugation among the Infusoria.[14]—Among the newer researches which throw light upon this old problem, those of Maupas are certainly the most brilliant. After a most exact and arduous research, extending over several years, he collected his results in two memoirs, published in 1889 and 1890.

His experiments were first directed upon the laws of direct multiplication by fission, or *direct division of the cell.* These revealed a complete cycle of life without conjugation in the single-celled Infusoria, and showed that after a long period this mode of reproduction becomes less vigorous, then declines, and finally ceases altogether unless the stock is rejuvenated by union with individuals of different broods, or *conjugation.* In other words, these broods of minute organisms grow old and die unless they are enabled to fertilize each other by an exchange of hereditary substance altogether analogous to that observed in the higher multicellular organisms.

The cultures were made in a drop of water upon a slide, and feeding was adapted either to the herbivorous or carnivorous habits of the species. Under these conditions it was found that the rate of fission, or direct reproduction by division, varied directly with the temperature and food, rising in some species (*Glaucoma scintillans*) to five bipartitions daily. With the optimum of conditions this rate, if sustained for thirty-eight days, would produce from a single individual a mass of protoplasm equivalent to the volume of the sun. This rate was, however, found to be steady for a time, and then the offspring decline into "senescence," in which they appear at times only one-fourth the original size, with reduced organs and degenerate nuclear apparatus. This is reached sooner in some species than in others; *Stylonichia pustulata* survives three hundred and sixteen generations by fission, while *Leucophrys patula* persists to six hundred and sixty generations. Finally, even under the most favorable conditions of environment, death ensues.

Death does not ensue where conjugation is facilitated by mingling the offspring of different broods in the same fluid, as in the natural state. Maupas soon discovered that exhaustion of food would hasten conjugation between members of mixed broods. He thus could watch every feature of the conjugation process, and determine all the phases in the cycle of life. These differed, as in the longevity of the species. In *Stylonichia*, for example, "immaturity" extended over the first one hundred bipartitions; "puberty," or the earliest phase favorable to conjugation, set in with the one hundred and thirtieth bipartition; "eugamy," or the most favorable conjugation phase, extended to the one hundred and seventieth; then "senescence" set in, characterized by a sexual hyperæsthesia in which conjugation was void of result or rejuvenescence, owing apparently to the destruction of the essential nuclear apparatus.

Conjugation begins with the approach of two individuals, and adhesion by their oral surfaces. There is no fusion, but an immediate transformation in the cell contents of each individual sets in, concluding with an interchange of nuclear substance. In each cell Maupas

distinguishes between the (*M*) *meganucleus* (Fig. 235; the macronucleus, nucleus, endoplast of authors), which presides over nutrition and growth, and divides by constriction, and the (*m*) *micronucleus* (paranucleus, nucleolus of authors), which presides over the preservation of the species. The latter contains chromatin; it is the seat of rejuvenescence, the basis of heredity, it divides by mitosis, showing all the typical stages of karyokinesis excepting the loss of the cell membrane.

The transformation in each of these copulating cells first affects the centres of hereditary substance, viz., the micronuclei; they divide three times; thus the micronuclear substance is reduced to one-fourth of its original bulk. It is contained in two surviving micronuclei (the others being absorbed or eliminated), one of which migrates into the adjoining cell; the other remains stationary. This migration is followed by a fusion of the migrant and stationary micronuclei; this fusion effects a complete interchange of hereditary substance, after which

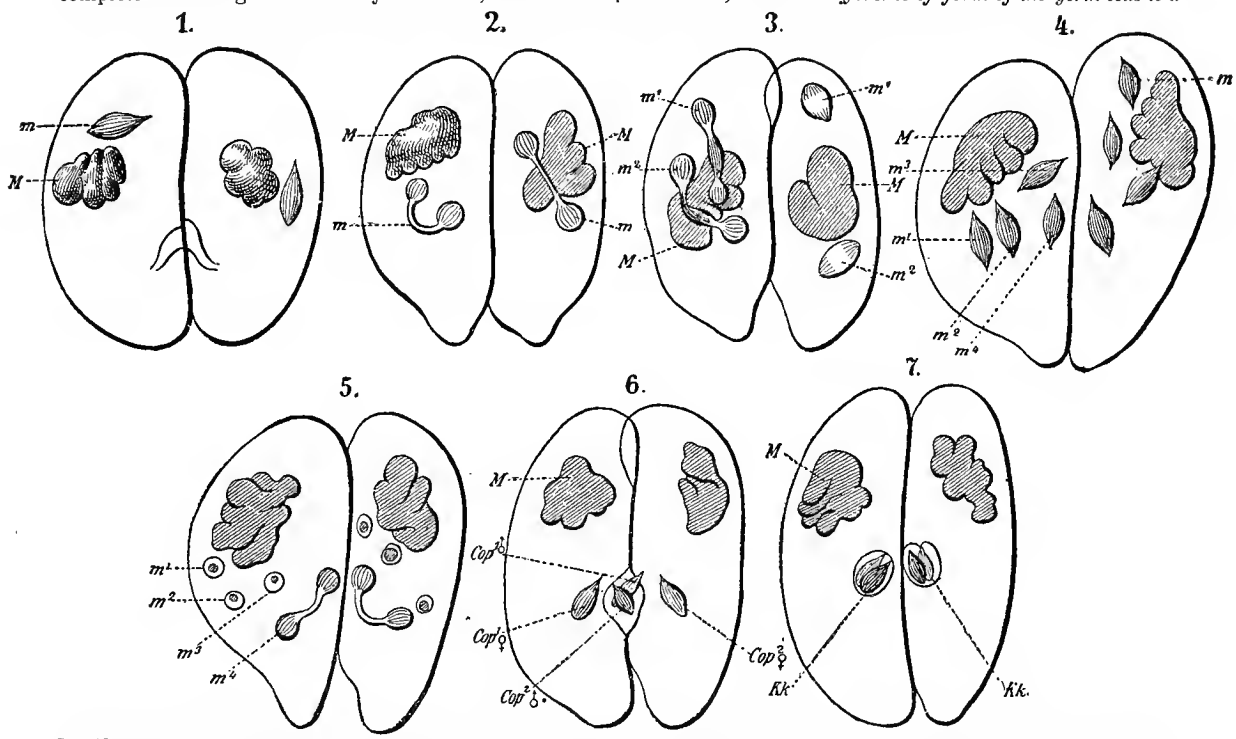

FIG. 235.—The Conjugation of Infusoria. (From Weismann, after Maupas.) 1, Two infusoria copulating; *M*, meganucleus; *m*, micronucleus; 2–5, successive divisions of micronuclei; 6, fertilization by the migration of one of the persisting micronuclei from each infusorian into the other; 7, union of the interchanged micronuclei.

the two infusoria separate and enter upon a new life cycle. Meanwhile the meganucleus breaks up and is reconstituted in each fertilized cell.

Maupas gathers from these interesting phenomena additional proof that the chromatin of all cells bears the inherited characteristics, and that the cytoplasm and nucleoplasm, or achromatin, is the dynamic agent, because the micronuclei bearing the chromatin * are the only structures which are permanent and persistent, all the other structures — nucleoplasm, cytoplasm, etc. — being replaced and renewed. The reduction of the chromatin is purely quantitative, the eliminated and fertilizing micronuclei being exactly equivalent; after the chromatin has been quartered the cell becomes incapable of further activity until it is reinforced by chromatin from the other copulating cell.

No Distinction between the Sexes in Heredity.—The three laws which underlie these phenomena are: 1. That fertilization consists in the union of the hereditary substance of two individuals. 2. That before union the hereditary substance in each is greatly reduced. 3. That there is no real line between male and female, the conjugating cells are simply in a similar physiological condition wherein a mingling of hereditary characteristics affords a new lease of life. As Maupas says:

"Les différences appelées sexuelles portent sur des faits et des phénomènes purement accessoires de la fécondation. La fécondation consiste uniquement dans la réunion et la copulation de deux noyaux semblables et équivalents, mais provenus de deux cellules distinctes."

In this conclusion as to the secondary and superficial, rather than fundamental, difference between the two sexes, Maupas simply confirms the views of Strassburger the botanist, Hensen, R. and O. Hertwig, Weismann, and others, namely, *that sex has evolved from the necessity of cell conjugation; that even in the higher forms the cells born by the two sexes are absolutely neutral so far as sex is concerned; the wide difference of form of the germ-cells is a result of physiological division of labor*—the mass and yolk of the *ovum* having been differentiated to support the early stages of development, while the *spermatozoon* has dispensed with all these accessories and acquired an active vibratile form for its function of reaching and penetrating the ovum. The evidence of the Infusoria is paralleled among some of the plants, in which conjugation between entirely similar cells is observed.

Sexual Conjugation.—As noted above, in higher types of animals in which the sexes are different, the ovum and spermatozoon differ widely in external form; this is because the ovum is a food-carrier and is passive while the spermatozoon is active, and, so far as we know, merely a carrier of hereditary substance. The ovum is sometimes found a million times larger than the spermatozoon, but the materials concerned in heredity in each are now believed to be exactly equal.

The various processes through which these two cells pass before and after conjugation are technically known as:

1. Ovogenesis and Spermatogenesis-Reduction of Here-

* For the meaning of these terms see the following section.

ditary Substance: Preparation of male (sperm) and female (ovum) cell for conjugation.

2. Fertilization-Union of Hereditary Substance: Union of certain elements in male and female cells into a new single cell. Or union of maternal and paternal hereditary elements.

3. Embryonic Development-Distribution of Hereditary

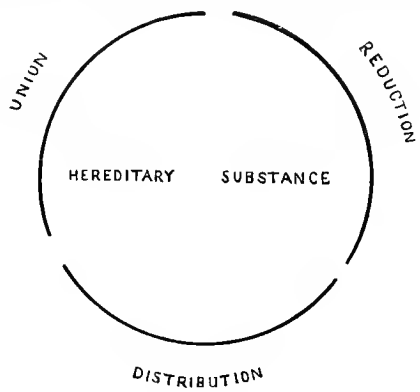

FIG. 236.

Substance: Division of the fertilized ovum (oösperm) into the cells of the tissues.

This is a complete cycle of changes, for among the embryonic cells from the oösperm soon appear the germ-cells in which we observe a fresh ovogenesis or spermatogenesis. Now what elements enter into these changes? The older topography of the ovum as a typical cell is very well known; there is first the (*a*) *cell-wall*, and within this the cell-protoplasm or (*b*) *cytoplasm*. In the centre of the cell is the (*c*) *nucleus*, containing its protoplasm or (*d*) *nucleoplasm*. Flemming was the first to show that suspended in the nucleoplasm is a special highly staining form of protoplasm which he called (*e*) *chromatin*, and still more recently it has been found that on one side of the nucleus, in the cytoplasm, are suspended one or two small special centres or (*f*) *centrosomes*.

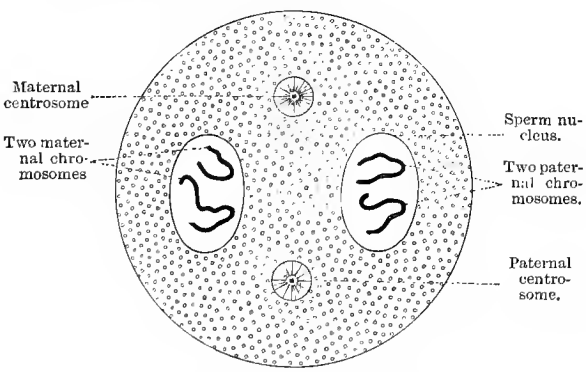

FIG. 237.—Oösperm prior to Union of Maternal and Paternal Elements.

The *chromatin* presents the appearance of a fine network in the interior of the nucleus when the cell is quiescent, but when the cell is dividing it is drawn out into a number of fine compact threads or *chromosomes* (Waldeyer), as shown in the accompanying figures. An equal quantity of chromatin is found in the ovum nucleus and sperm nucleus, and this is now believed to be the *material basis of heredity*. The chromosomes are concerned in all cell life, and are considered qualitative.

The *centrosomes* are specific bodies lying in the cytoplasm outside of the nucleus, and moving to its opposite poles only during division. As proved in "polyspermy," these bodies are also found in both ovum and sperm-cells; they are now believed to represent the *active dynamic and regulative material* of the cell. The centrosome is apparently the active agent in every cell division throughout life.

We may begin at any point in the cycle of development. In order to understand most clearly the respective

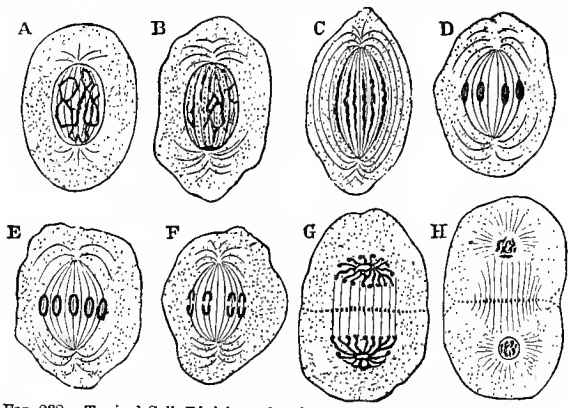

FIG. 238.—Typical Cell Division, showing the Distribution of Chromatin. (From Parker, after Carnoy.) A–C, arrangement of the chromatin; D–E, formation of the chromosome rods and loops; F, splitting of the loops; G–H, retraction of the chromatin into the two daughter-cells.

functions of the *chromatin* and *centrosomes* let us first consider embryonic development and observe the mechanism by which the chromatin is evenly distributed to every cell of the body.

a. Distribution of Hereditary Substance.—The starting-point of distribution is the oösperm (fertilized ovum). This contains chromatin and centrosome elements from each parent, as shown in the accompanying figure. The chromatin is contained in four chromosomes (the number characteristic of the species); two of these chromosomes come from the sperm-cell and two from the ovum-cell. These chromosomes are kept separate in the first stages, and then united in one coil, Fig. 239. The centrosomes

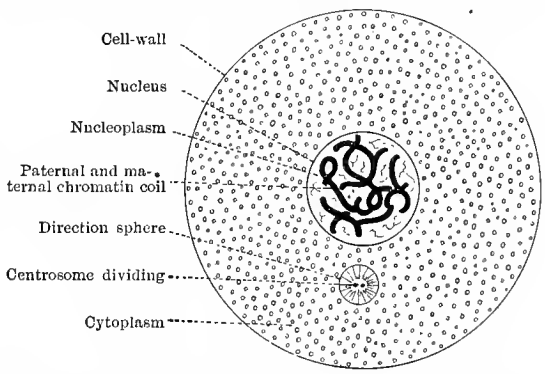

FIG. 239.—First Stage after Union of Maternal and Paternal Elements.

are believed to unite and combine maternal and paternal elements from the start.

The phenomena of karyokinesis which attend the division and distribution of this hereditary substance throughout the whole course of embryonic and adult development are well illustrated in Carnoy's figures (Fig. 238). First we have the quieseent period, in which the chromatin presents the appearance of a coiled, tangled thread; surrounding this is the clear nucleoplasm (or achromatin) bounded by the nuclear membrane; the extra-nuclear substance, or cytoplasm, is apparently undifferentiated. As soon as cell division sets in, however, radiating lines are seen in the cytoplasm above and below the nucleus, these are called the centrosomic filaments, since they pro-

ceed from the two centrosomes (Fig. 240). As the activity becomes more intense the filaments are seen to diverge from a centre—the plasmic *centrosome*—which lies just without the nucleus at either pole; this radial display of

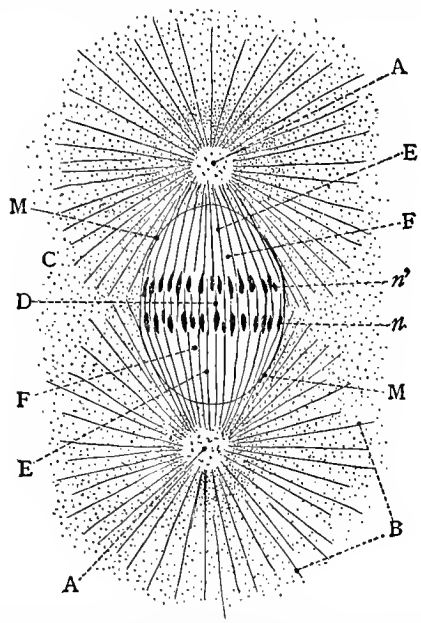

FIG. 240.—The Central Portion of a Tissue-cell during Division. Differentiation of the Cytoplasm and Nucleus of a Squid Embryo, Loligo. (After Watase.) M, the nuclear membrane; F, achromatin or nucleoplasm; C, cytoplasm or protoplasm outside of the nucleus; A–A, the two centrosomes; B, extra nuclear centrosome filaments; E, intranuclear centrosome filaments attached to *n*, *n'*, the chromatin rods.

cell-forces suggested the term "asters" to Fol, and "spheres attractive" to Van Beneden; they may here be called *direction spheres*. The behavior of the chromatin, or hereditary substance, under these forces, is

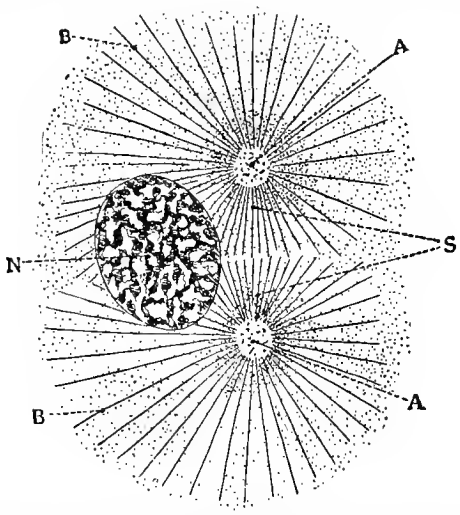

FIG. 241.—After Division. Interior of a Daughter-cell in the Squid. (After Watase.) Division has just taken place and the daughter-nucleus, N, shows the chromatin coil. The daughter centrosome is just forming two new centrosomes, A–A, by direct division.

shown in Carnoy's diagrams (Fig. 238). First, the nuclear wall breaks up, then the chromatin coil unfolds into lines of vertical striation which become thread-like (hence the term mitosis), and then more compact, until finally a number of distinct vertical rods, chromatin rods, or *chromosomes*, are formed.

A remarkable and significant fact may be noted here, that *the number of chromosomes* varies in the cells of different species, and even in the cells of different varieties (as in the thread-worm of the horse—*Ascaris megalocephala*), *but in each variety the same number is constant in all the cells of each individual through all stages*; thus the same number of chromosomes appears in the first segmentation of the fertilized ovum as in all the subsequent cell division in the tissues.

Carnoy next indicates the vertical splitting of each rod into a loop or link preceding the horizontal splitting; thus we may conceive of a thorough redistribution of the chromatin before it passes into the daughter-cells. The split loops are each retracted toward a centrosome, suggesting to some authors a contractile power in the centrosomic filaments; each chromasome being apparently withdrawn by a single filament. The chromatin is again retracted into two coiled threads, each the centre of the daughter-nucleus with a single centrosome beside it. But when the line of cleavage is drawn between the two cells (Fig. 238), the single centrosome in each cell divides so that each daughter-cell is now complete with its chromatin coil and two centrosomes. This process has been well figured by Watase[1] (Figs. 240 and 241).

It thus appears that both the chromatin and centrosome are permanent elements of the cell, such as we formerly considered the nucleus; the apparently passive chromatin is divided with great precision by the active centrosomes, then the centrosomes simply split in two to resume their cleavage function. Each chromosome and each centrosome is separate—these two elements are apparently passed down distinct from generation to generation.

The theoretical meaning of this distribution process will now be discussed. The whole process can be very clearly followed in Figs. 237, 239, 240, 241, 242, 243.

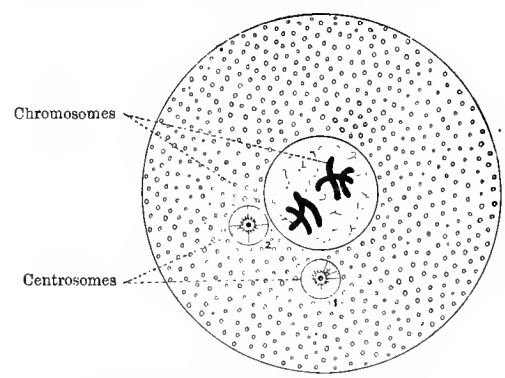

FIG. 242.—Second Stage. Division of Centrosome.

The Nature of the Hereditary Substance in each Body-cell.—There still remains to be considered the relation of the hereditary substance to the future development of the individual. There is some reason to believe that each cell of the body contains not only the characters of the special tissue to which it belongs, but other characters. There is first the astonishing fact that, as the chromatin goes on dividing, its mass or volume remains apparently undiminished. That is, there is apparently as much chromatin in one of the many million active cells of the body as in the original fertilized ovum, and we face still the enigma as to the nature of this chromatin and its functions.

1st. In plants De Vries[16] and others believe that all or by far the greater number of cells in the plant body contain the total hereditary characters of the species in a latent condition. Kölliker[17] has fully discussed this question and called attention to Müller's early views that, in spite of the physiological division of labor producing the tissues, the properties of all the tissues can be derived

from the nuclear substance of a single tissue, as proved by experiments upon the lower animals. According to this idea there is only a *quantitative* distribution, the chromatin increases in bulk, and each tissue only calls forth certain of its powers. Weismann, on the other hand, has held that the course of development is marked by a constant *qualitative* distribution of his germ-plasm or hereditary substance, so that each tissue finally contains only the hereditary substance which belongs to it and the total hereditary substance or germ-plasm goes only to the new ova and spermatozoa. Kölliker opposes this idea and maintains that the hereditary substance, or "idioplasm," passes into all cells, in which it divides in course of development; step by step, from the embryonic layers to the tissues, the constructive processes are under the direction of the nuclei containing this hereditary substance; it remains in every nucleus for a long period unaltered, in order to finally, here earlier, there later, impress its peculiar constructive forces. In certain elements, as in blood-corpuscles, epidermal scales, etc., it disappears, as the last product of division.

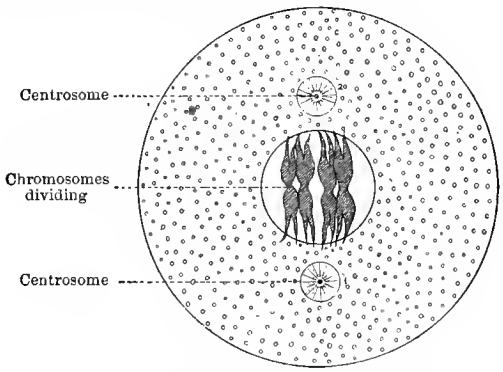

FIG. 243.—Third Stage. Division of Chromosome.

Hertwig takes a similar view; since embryonic and adult cell division is differential there must be a form of differentiation in the nucleus, but this does not consist in the total elimination of some qualities and survival of others, nor of a reduction in mass. The mass and the properties remain the same in every cell, the differentiation consists in the activity of certain elements in certain tissues. The potential of the nuclear substance is differently exerted at different points. Here, again, we have the idea of patent and latent hereditary elements, such as appear in the entire individual upon a larger scale.

In the following paragraph Hertwig expressed his view of nuclear control and cytoplasmic differentiation:

"As I saw in the transformation of the nucleus during fertilization proof that it is the bearer of hereditary substance I recognized a great advance in the fact that the nucleus leaves in the same form in every cell, and in its vesicular capsule is somewhat removed from the metamorphoses of the cells. As Nägeli spread his idioplasm as a net-work throughout the whole body, so, according to my theory, every body-cell contained in its nucleus its quota of hereditary substance, while its specific histological peculiarities were to be regarded as its plasma-products."

2d. The next question *is the fate of the maternal and paternal contributions to the embryo:* are they fused or do they lie side by side? Here there is a wide difference of opinion.

We have seen that in the oösperm (Fig. 237) the maternal and paternal chromosomes are entirely separate, but as soon as this cell divides into two, the maternal and paternal chromatin forms an intimate net-work. On the one side Van Beneden is the leader of those who regard each cell of the body as in a sense hermaphrodite; as we have seen, his views of maturation and the significance of the exclusion of the polar bodies were colored by this theory, for he regarded the germ-cells as hermaphrodite until one sex was eliminated. But now that the researches of Hertwig have given the last blow to Van Beneden's theory, and it follows that there can be no sexual difference in chromosomes, there remains room for the analogous view that the maternal and paternal chromosomes remain distinct throughout the course of development, not as sexual elements but as substances with different hereditary tendencies. Rabl, an eminent embryologist, shares this view, and it is supported by Boveri upon the observation that in each division the paternal and maternal elements are kept distinct, and in *Ascaris*, for example, two of the chromosomes of each division figure are paternal and two are maternal. In favor of this hypothesis we may place the following facts: 1st, That there are an even number of chromosome rods in all cells; 2d, that the number is constant throughout all the subsequent changes in the tissues; 3d, that the number is fixed for each species or variety; 4th, that the number is the same in each sex.

Against this *non-fusion* hypothesis we must consider

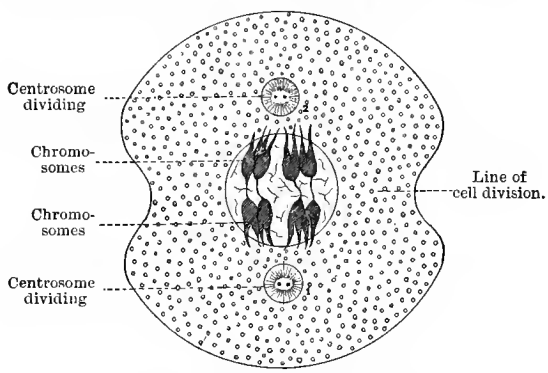

FIG. 244.—Fourth Stage. Division of Cell-wall.

the extreme complexity of the division process, and the long-intermediate resting, or thread stage, in which the chromatin lies in a confused coil. Hertwig advocates a *fusion* hypothesis and argues that if the elements are distinct we should find some evidence that the maternal or paternal part is atrophied or replaced, or excluded from the nucleus, for both parts cannot share alike in the control of the cell. Such are his grounds for supporting the "Versehmelsungstheorie," or *fusion* theory, also advocated by Waldeyer, to the effect that by the complete union of the maternal and paternal substance a new product is formed; in this fusion the law of prepotency may come into play, causing one or other of the parental tendencies to predominate, or there may be an even redistribution, whereby, as expressed by Hensen, "the hereditary substance of the son is not that of the father plus that of the mother, but is his own, with a new hereditary form resulting from the combination."

While suspending judgment between these two views as to the fusion or non-fusion of the hereditary substances, we may appeal to the external phenomena of heredity for light upon the probabilities in the question. First, we have the very decided opinion of Francis Galton in regard to particulate inheritance; he is so impressed with the fact that we are made up bit by bit of separate structures derived from different ancestors that he has even suggested that the skin of the mulatto may represent not a fusion of white and black but an excessively fine mosaic in which the colors are so distributed as to give the appearance of blending. We do sometimes observe patches of color as evidence of uneven distribution. As Galton distinguishes two types of structures with reference to inheritance, viz., those which blend and those which do not blend, we might correlate these types with prepotency, replacement, and fusion. Where characteristics do not blend, as in eye-color, it is evident that, while the offspring must receive from both

parents the material basis for the formation of the complete color of the eye, either the maternal or paternal material must be prepotent and exclude the development of the other; the logical inference is that the former actively replaces the latter; but it is not necessary that exclusion from the cell-chromatin should follow. Now, while some blends seem to support the theory of fusion, the sum total of facts of heredity are strongly against this as a universal principle, for many maternal and paternal structures are preserved in their absolute integrity for generations without the least indication of mixture.

b. Reduction of Hereditary Substance.—By the above "distribution" the chromatin is constantly increasing in quantity, because an equal amount passes into every cell of the body. The embryonic sperm and ovum cells receive their share, it follows that originally each has the chromatin complement of a complete cell; part of this must be gotten rid of, otherwise the oösperm will represent not one cell but two cells. It has long been known that the ovum is prepared or "matured" for the reception of the spermatozoon by the extrusion of two small "polar bodies," containing both chromatin and hyaline protoplasm, and separating off by karyokinetic division. From this it appears that before fertilization the original amount of chromatin is reduced in quantity. For twenty-five years speculation has been rife as to why the ovum should extrude a portion of its substance in two small cells. Why not in one cell? why not in a larger number? Thanks to the intense curiosity which these polar bodies have aroused, and to the great variety of explanations which have been offered for them, we have arrived to-day at a solution which links the higher animals with the lower, breaks down the supposed barrier between the sexes, and accords with the main external facts of heredity.

It seems best to disregard the order of discovery, and to state the facts in the most direct way. First, a few words as to the speculations upon the meaning of the polar bodies.

The early theories of the meaning of sexual congregation or fertilization[1] were naturally based upon the apparent significance of this process in the human species, in which the sexes are sharply distinguished from each other in their entire structure, and the reproductive cells are also widely differentiated in form, the ovum large and passive, the spermatozoon small and active. It was most natural to regard these elements as representing distinct physiological principles, corresponding to the essential sexual characteristics—in short, as male and female cells, the former vitalizing and rejuvenating the latter. Thus one of the earliest definite "polar-body" theories was that the embryonic ovum was hermaphrodite, and contained both male and female principles, and that it was necessary to get rid of the male substance before the spermatozoon could enter.

As Von Siebold and Leuckart had demonstrated that some ova reproduce parthenogenetically, that is, without fertilization by spermatozoa, Weismann turned to such forms for the solution of this problem, and was surprised to find that parthenogenetic ova only extrude one polar body; this led him to attach one meaning to the first polar body, and another meaning to the second, which he viewed as designed to reduce the hereditary substance in the ovum without regard to sex. Thus both this and the older theory conveyed alike the idea of *reduction*, but with an entirely different supposition as to the nature of the material reduced or eliminated.

The Modern Theory of Reduction.—Van Beneden's discovery that these bodies contained chromatin led gradually to the view that they were not fragments of the ova, but represented minute, morphologically complete, cells. Bütschli showed that they were given off independently of, and prior to, the contact of the spermatozoon, and, finding in the leeches that the first polar body subdivides to form two bodies, he considered them as formed by true cell division, and containing both nucleoplasm and chromatin. Giard independently reached a similar opinion, assigning an atavistic meaning to the polar cells. Whitman, in 1878, advanced the idea that they represented vestiges of the primitive mode of reproduction by fission, while Mark described them as "abortive ova."

At this point speculation subsided until it was revived by Weismann's attempt to connect these bodies with his theory of heredity,[19] already referred to. The whole history is clearly given in R. Hertwig's masterly memoir upon Ovo-and Spermatogenesis in the Nematodes.[20] Taking advantage of Boveri's discoveries in staining technique, and stimulated by Weismann's prediction that spermatozoa would also be found to extrude polar bodies,

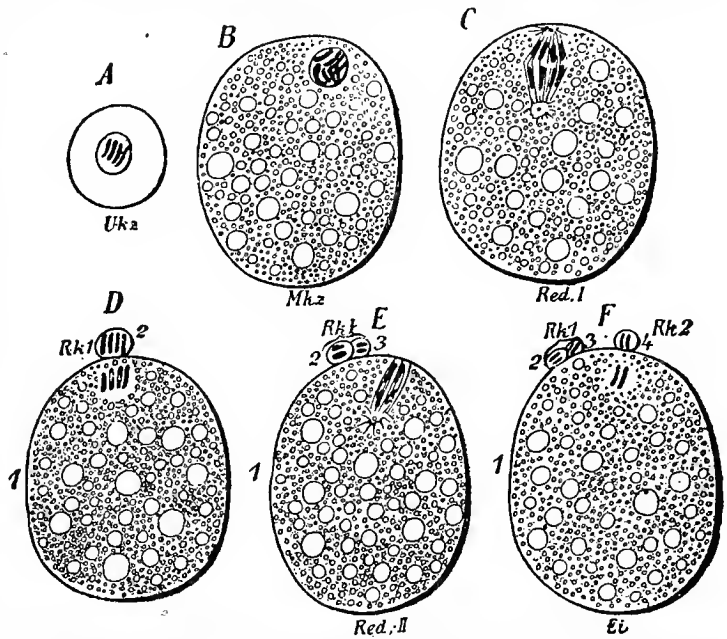

FIG. 245.—The Maturation of Ova, or Formation of Polar Bodies in Ascaris. (From Weismann, after Hertwig.) *A*, original germ-cell in embryonic germ-layer—4 chromatin rods; *B*, ovum mother-cell—8 rods; *C–D*, first polar body extruded; *E*, splitting of first polar body—ovum still contains 4 rods; *F*, second polar body extruded—ovum mature with 2 rods.

this author examined all stages in the peculiarly favorable germ-cells of the thread-worm of the horse (*Ascaris megalocephala*).

He made the surprising discovery that ova and spermatozoa are formed in a substantially similar manner by repeated divisions, the single difference being that the last products of division among the sperm-cells are effective spermatozoa, capable of development in fertilization, while the last products of division in the ovary are, first, the true ova, and second, the abortive ova (polar cells) incapable of development. In both ova and spermatozoa, when ready for union, the nucleus contains but one-half the chromatin which a typical nucleus contains; in the case of *A. megalocephala* (see Fig. 245) each of the germ-cells contains but two chromosomes, while the normal body-cells contain four. The manner in which this maturation of the germ-cells for conjugation is brought about is beautifully shown in these diagrams, taken from Weismann's essay, "Amphimixis." We observe that the number of chromosomes in the primary germ-cells is four (Figs. 245 and 246, *A*). Then are formed by subdivision the ovum and sperm "mother-cells," in which the chromatin substance is doubled, so

that we observe eight chromosomes. The mother-cells then divide and the chromatin is reduced to four rods ; a second division rapidly follows, whereby the chromatin is reduced to two rods, or half the original quantity. These last divisions take place by karyokinesis, but, as Hertwig points out, they differ from typical karyokinesis in the fact that the divisions follow so rapidly upon each other that the vesicular resting-period of the nucelus is omitted. Thus, he suggests, is prevented an over-accumulation of chromatin substance prior to the fusion of the ovum and sperm.

It is evident that the polar-cells are rudimentary ova, which do not possess the yolk-mass, etc., essential to development, and are divided off at a very late stage, sometimes after the egg has left the ovary, but are in other respects analogous to the spermatozoa. The reason why these polar-cells have not disappeared altogether in either plants or animals is that they originally possessed a deep physiological importance. As the first polar-cell subdivides and forms two, it follows that from both ovum and sperm mother-cells four daughter-cells are formed, each containing half the chromatin substance of a normal nucleus. In the ovary three of these daughter-cells abort and the fourth forms a true ovum ; in the sperm-gland, however, all four daughter-cells form spermatozoa.

We may thus consider the polar-cell problem as in all

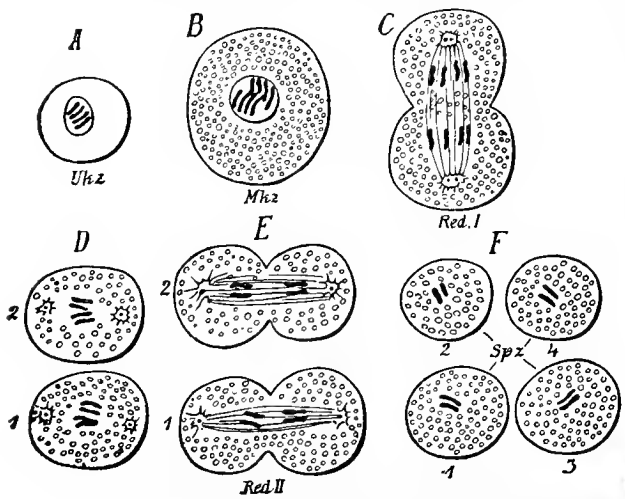

FIG. 246.—Spermatogenesis in Ascaris. (From Weismann, after Hertwig.) *A*, original germ-cell—4 chromatin rods ; *B*, sperm mother-cell—8 rods ; *C-D*, first daughter-cells, with 4 rods each ; *E-F*, formation of second daughter-cells, or mature spermatozoa, with 2 rods each.

probability settled ; the whole process is probably an inheritance or survival of a primitive condition in which all four ova, like all four spermatozoa, were fully functional.

The Relation Between the Reduction of the Chromatin Substance and Heredity.—We have just seen that the last stages in the preparation of the ova and spermatozoa for conjugation result in halving the number of rods in the original germ-cells. Now, as Hertwig and Weismann point out, one point is still left in doubt. Why is the chromatin substance doubled in the mother-cells so that two successive subdivisions are necessary to reduce it to half the original quantity ? Hertwig has not attempted to answer this question, as he prefers to wait for further research. Weismann, however, who is unfortunately cut off from research by failing eyesight, has offered a speculative solution to this problem which he trusts may guide future investigation.

This leads to a few words in regard to his conception of the relation of the chromatin to heredity. 1. His first premise is that in fertilization there is not a fusion of chromatin, but that a certain independence is preserved between the maternal and paternal elements, based upon the observed fact that the two pairs of rods do not fuse, but lie side by side, and upon the assumption that these pairs are kept distinct in each cell through all the subsequent stages of embryonic and adult development. If this is the case, the hereditary substance contributed by the father would remain separate from that contributed by the mother, throughout. 2. "Each of these pairs would be made up of the collective predispositions which are indispensable for the building up of an individual, but each possesses an individual character, for they are not entirely alike. I have called such units 'ancestral plasms,' and I conceive that they are contained in numbers in the chromatin of the mature germ-cells of living organisms, also that the older nuclear rods are made up of a certain number of these. . . . Obviously these units cannot become infinitely minute ; however small they may be they must always retain a certain size. This follows from the extremely complicated structure which we must without any doubt ascribe to them." These units are not, however, ultimate, they are in turn extremely complex, and are composed of countless biological units of the kind conceived of by Nägeli and others. 3. The reduction of the chromatin only acquires a meaning when taken in connection with the above supposition of distinct ancestral plasms, and has no meaning if we accept Hertwig's view that there is a complete fusion of maternal and paternal germ-plasm. This meaning is that reduction in the maturation of germ-cells is *sui generis*, it does not divide the ancestral plasms into two similar groups, but one daughter-cell receives one set of germ-plasms or hereditary predispositions, and another daughter-cell receives another ; reduction is thus differential. According to this view the four sperm and ovum daughter-cells would each contain a different set of ancestral plasms. 4. The fact that the chromatin substance is doubled in the sperm and ovum mother-cells, so that we observe double the number of rods characteristic of the species, is to be explained as an adaptation to the requirements of natural selection, for this doubling and subsequent double division render possible an infinite number of combinations (as many, in fact, as there are individuals) for Selection to operate upon.

This explanation of Weismann's is an example of his apotheosis of the theory of natural selection. Every process is made to suit this theory, which, as we have seen in the section on Speculative Heredity, is, in his opinion, the exclusive factor of evolution. But this very high degree of mingling and remingling of ancestral predispositions would be fatal to evolution, for after a combination favorable to survival had been established in one generation it would be broken up into a new combination, perhaps unfavorable to survival, in the next generation. His entire essay upon "Amphimixis," or the theory of mingling of reduced hereditary substance, marks a turning-point to decline in Weismann's influence as a biologist. His whole reasoning is now in a circle around the natural-selection theory.

C. *Union of Hereditary Substance—The Meaning of Conjugation.*—Weismann looks upon sexual reproduction as designed to mingle hereditary tendencies and to create individual differences whereby natural selection may form new species. It is evident that such combinations must be mainly fortuitous and productive of indefinite variations.

The fact, however, that variability and evolution by the accumulation of certain variations in successive generations is also observed in organisms which reproduce asexually, both among plants and animals, shows that we must look in another direction for the underlying cause or purpose of sexual reproduction. Weismann rightly combats the old idea of *vitalization* of the ovum by the spermatozoon, and it is perfectly evident from the researches of Maupas and Hertwig that the ovum may as accurately be said to vitalize the spermatozoon as the reverse. Conjugation is simply the approximation of two hereditary substances of distinct origin and their incorporation into a single cell destined to give rise to a new individual. The action and reaction of

these substances may be considered equal and mutual, so far as we now know.

The remarkably ingenious experiments of Hertwig and Boveri, above alluded to, strengthen this idea. Some years ago Weismann wrote: "If it were possible to introduce the female pronucleus of an egg into another egg of the same species, immediately after the transformation of the nucleus of the latter into the female pronucleus, it is very probable that the two nuclei would conjugate just as if a fertilizing sperm-nucleus had penetrated. If this were so, the direct proof that egg-nucleus and sperm-nucleus are identical would be furnished." Boveri succeeded in accomplishing a similar feat by shaking an ovum and thus depriving it of its nucleus and subsequently admitting *a spermatozoon which fertilized the denucleated ovum and produced a complete individual!*

Weismann goes further, and maintains that there is nothing in the nature of vitalization or "rejuvenescence" in conjugation—that, given proper environment, protoplasm is immortal and runs upon a course of undiminished activity. This we have seen is not the case in the infusoria, and, as recently remarked by Hartog, there is only one class of organisms which, according to our present knowledge, are completely agamous and immortal, namely, the group which includes the bacteria. It may in future appear that even in these minute organisms there is a cycle of development in which conjugation plays its part.

Maupas's experiments seem to establish the interpretation of the purpose of conjugation as well as of sex, the latter being a consequence of the former, namely, that after a long period of direct subdivision of hereditary material from a single individual, a limit is reached beyond which the forces of heredity are not reproduced in their original intensity unless combined with another set of similar forces of different origin. This combination restores the original intensity. It is objected to this that two sets of feeble forces cannot constitute one vigorous force, but this is met by the observed fact that such union does start a new life cycle, and is therefore rejuvenescent. We may regard this as the fundamental meaning of conjugation and the production of variations as entirely secondary.

6. Experimental Embryology.—Experimental embryology plays the rôle of experimental physiology and vivisection upon the ovum, spermatozoon, oösperm, and embryo. The idea is to discover normal laws and relations by setting up abnormal relations. Thus the Hertwig brothers for many years experimented upon the ovum during the conjugation period with drugs and extremes of temperature and found that when the regulating forces in the ovum are artificially suspended abnormal conjugation and development results. Following the gravity experiments of Pflüger, Roux has opened up a new branch of embryology in his "Entwickelungsmechanik," or the science of the combinations of vital energy which produce development by studying the influence of gravitation, light, heat, and magnetism upon the embryo.[21] Roux has also practised the extirpation method by removal of portions of the embryo. Verworn has also practised extirpation upon the infusoria,* or single-celled organisms. A third line of experiments has been introduced by Driesch and Wilson by shaking the embryo in the two- and four-cell stage, and thus producing out of a single oösperm from two to four complete individuals. Some of the results of these various methods may now be briefly summarized.

a. Relation of Nucleus to Cell.—After a long series of experiments, Verworn reaches the conclusion that the *nucleus* is not a dynamic or force centre, either automatic or regulating, but the nucleus combined with the extra nuclear protoplasm must be the seat of heredity. He compares the rôle of the nucleus with that of a cell organoid, like the chlorophyll of plant-cells, as not constantly present but as neeessary to activity. This conclusion coincides with the prevailing theory we have outlined as to the relations between the chromatin (within the nucleus) and centrosomes (without the nucleus), although Verworn, working upon living cells, naturally could not separate either of these elements, which are only brought out by staining.[22]

b. Abnormal Fertilization or Polyspermy.—In the normal state the entrance of a single spermatozoon produces a reaction in the ovum-wall preventing the entrance of other spermatozoa, but when the ovum is weakened by chloroform solution, also by morphine, cocaine, curare, and other poisons, two or more spermatozoa enter before the reaction appears; in fact the degree of polyspermy is directly proportional to the intensity of the chemical, thermic, or mechanical disturbance of the ovum. Nicotine and strychnine seem to increase the activity of the spermatozoa. *Double fertilization* or over-fertilization *has not in a single case resulted in the production of twins*, so that Fol's supposition is negatived, although other forms may behave differently. Fol supposed that single, double, or multiple births might be proportionate to the number of spermatozoa entering the ovum. The effect of over-fertilization is to produce a number of karyokinetic figures, or spindles (see Fig. 238, illustrating "typical cell division") within the oösperm instead of one; the normal cell division runs riot, and no complete individuals are produced. The cell-division may be arrested at any stage by thermic influences; thus two pronuclei, paternal and maternal, about to unite can be held apart in an oösperm, by lowering the temperature. Polyspermy also results from a lowered temperature. It is noteworthy that the conditions of bastard fertilization (fertilization by sperm of another variety of animal) and polyspermy are different; chloroform produces the latter, but not the former.

The latest researches upon polyspermy are those of Rückert. He has made the surprising observation that in some fishes the penetration of more than one spermatozoon into the ovum is a normal process. But a single sperm nucleus unites with the ovum nucleus to form the main tissues of the body, while the other sperm nuclei combine with certain elements in the ovum and form the parablast, an embryonic layer whose history has always been doubtful.

c. The Production of Twins and Double Monsters.—See Driesch in the embryos of starfish, Hertwig in the same form, and Wilson in the embryos of the lancelet (*Amphioxus*, the lowest animal in the vertebrate scale). Wilson's experiments are the latest. He produced, with perfect ease, embryos from one-half to one-eighth the natural size, and corresponding in number from two to eight, by shaking the early embryo in its various stages of division from two to eight cells. Thus just after the oösperm has divided into two cells, shaking produces two quite separate and independent twins of half the normal size. These embryos develop into free swimming larvæ, but do not live more than a day. Shaking in the four-celled stage produces embryos which live a much shorter time. In the eight-celled stages the embryos develop but die before invagination. If the embryonic cells are more or less *incompletely separated*, we find a series leading from scarcely bilobed forms to those in which two nearly perfect bodies are joined by only a narrow bridge of tissue.

Here we have a hypothetical key to the mode of formation, both of twins and of double monsters.[24]

d. Dynamics of Embryonic Development.—This line of research has not as yet been brought to a stage in which its bearings upon heredity are so obvious as in the above phenomena. The main conclusions from the researches of Pflüger, Born, Hertwig, and Roux are that development is due to forces within the oösperm, which are powerful and independent enough to readjust themselves, if artificially thrown out of their normal relations, to external physical forces, such as gravity, light, heat, magnetism, etc. Yet there are two sets of forces to be considered in development: first, the internal self-differentiating, second, those interacting with the external environment.

The self-differentiating forces are very powerful in the early stages, and the ability to produce a whole is not divided between single cells. As we have seen above that each of the four cells of a single embryo lancelet is

capable of producing a complete lancelet, so Roux finds that when a portion of an embryo is destroyed, say by thrusting in a hot needle, this wound is healed, the part removed is regenerated, and a complete, though sickly, individual is produced. To take another case, if the embryonic region destined to form the tail is split in two, a pair of complete tails are sometimes produced, not two half tails.

On the other hand, Roux finds in some cases that if the cells are injured in early stages and not detached, the remaining healthy cells will produce only the regions of the body which they were normally destined to produce. Thus the four-celled stages mark a division into the four quarters of the future body, the right and left head end and the right and left tail end; suppose the right head and tail ends are injured, then the left head and tail ends produce a perfect half embryo. In some cases a more or less complete individual is produced by post-generation. Similar experiments have been conducted by Chabry [25] and reviewed by Andrews, who concludes that each half cell in the two-celled stage of embryonic division has for the main part all that the other has, and if the other be killed, not a half larva but a whole larva, deficient in only a few organs, will be produced.

e. Cross Fertilization.—Interesting experiments have been made by Boveri upon the production of bastards, or fertilization between ova and spermatozoa of different varieties. This was done by depriving the ovum of a sea-urchin of its nucleus by shaking in a test-tube; from the denucleated ovum of one genus (*echinus*) and the spermatozoon of another (*sphærechinus*) a larva of middle form is produced. But when a fragment of an ovum is fertilized, and this is found possible, a larva is produced with the character of the sperm only. This appears to prove that the spermatozoon conveys the power of forming a complete individual. These few examples of the kind of progress which is now being made in experimental embryology are sufficient to prove that the phenomena of teratology are largely seated in the conditions under which the ovum and spermatozoon unite, that fertilization during periods of alcohol, morphia, or nicotine poisoning may produce in the offspring of man results altogether analogous to those which we observe in these lower organisms.

Conclusions.

Heredity.—Perhaps the most impressive result of this review of recent researches in heredity is the uniformity of life-processes throughout the whole scale of life from the infusoria to man. Such uniformity furnishes a powerful argument for the advocates of the study of biology as an introduction to the applied science of medicine. Much that is now entirely omitted from medical education, because it is considered too remote, is in reality at the very roots of the science. To understand the disorders of life we should first thoroughly understand the essential phenomena of normal life. Of course we shall never see life as it really is, because there is always something beyond our highest magnifying powers; but we come nearest to this invisible form of energy when, with such investigators as Van Beneden, Hertwig, Boveri, and Maupas, we strip the life-processes of all their accessories and view them in their simplest external form.

The problems of evolution are found to be inseparably connected with those of heredity. No theory is at all adequate which does not explain both classes of facts, and we have seen that the explanations of hereditary processes offered by those who believe in the transmission of acquired characters and those who do not, are directly exclusive of each other. We should gather from every quarter facts which bear upon the most important and central problem of the transmission of acquired characters. Medical practitioners enjoy exceptional opportunities of contributing evidence upon this mooted question. It must not be forgotten that while the inheritance of the changes observed during life caused by various habits is the simplest method of explaining the evolution of man, we know absolutely nothing of how such changes can be inherited through the germ-cells. We cannot at present construct even any form of working hypothesis for the process which

> "shapes our ends,
> Rough-hew them how we will."

The Germ-cells.—1. The material substance of hereditary transmission is the highly coloring protoplasm, or chromatin, in the nucleus of the germ-cells, probably connected with the activity of the centrosome containing a certain form of dynamic protoplasm, outside of the nucleus.

2. Before conjugation and fertilization the hereditary substance of both the male and female cells is reduced to one-half that found in a typical cell. The substance is, however, first doubled and then quartered, the meaning of which process is not understood.

3. There is a difference of opinion as to whether the paternal and maternal hereditary substances, during fertilization, are fused or lie side by side; also as to how the substance is distributed through the tissues, whether *en masse* or by qualitative distribution. The balance of evidence seems to favor the view that the chromatin of each cell contains, besides its special characters, some of the general characters of the entire organism.

4. No physiological connection between the germ-cells and body-cells is known, but the facts of heredity seem to render such a connection theoretically necessary. Several classes of facts connected with reproduction seem to support this theory.

5. The facts of heredity support the theory of a continuous hereditary substance in protoplasm, as the basis of repetition of type, but do not favor Weismann's hypothesis that the germ-cells alone contain this hereditary material.

HERNIA. In Vol. VIII. of this work the writer discussed first the subject of strangulated hernia and its treatment, and then the accepted modern methods in attempting radical cure of hernia; a previous volume containing other methods than these more recent ones. Since the time when the article in Vol. VIII. was completed there have been devised in various parts of the world yet other herniał operations of interest. These and a few modifications of the thoughts which I formerly expressed render a further study of these subjects advisable.

Regarding strangulated hernia I have little to add. I endeavored in my previous article to point out, and wish here again to emphasize, the fact that the peril lies in delay and repeated and prolonged taxis, and not in the simple cutting operation to give relief. The patients who die do so not through any fault of the surgeon, but from the procrastination of the physician, who counsels waiting "just a little longer."

After a few hours have elapsed it is in most instances no longer a question between the surgeon and the physician, but between the surgeon and the undertaker.

I think it rather a common error in the profession to estimate the degree of the strangulation by the severity of the pain and tenderness. This rule is an unsafe guide.

I still think an hour sufficient time to devote to taxis and the various devices calculated to promote the success thereof.

Among these, one that I can recommend as sometimes of more value than application of ice, is spraying the swelling with ether. If no spray apparatus is at hand, pouring the ether on, a little at a time, and vigorously fanning, will also cause intense cold, and this acts favorably both by contracting the bulk of any gas within the strangulated loop of bowel and by relieving muscular spasm. The latter factor, considering the aponeurotic nature of the stronger constricting fibres—those of the external oblique muscle,—is not, at least commonly, of importance. Perhaps spasm of the internal oblique or transversalis muscles, at or near the deep ring, may occasionally be present and be relieved by the cold.

Poulticing and hot baths can hardly do good in any other way than this; and as they must necessarily increase the bulk of the gas, I now substitute the cold (by ether spray) instead.

It need hardly be said that aspiration of gas and of fluid fæces, through an aspirating-needle, might so readily be followed by septic infection in the track of the withdrawn needle as to make this plan a dangerous one.

Recent experience has inclined me to advise against the use of morphine in any cases of strangulation. Like the hot baths and poultices, morphine can only be of use by relieving a doubtful muscular spasm. And too often, by making the patient entirely comfortable, it seals his death-warrant. He cannot—in some instances—be made to realize that the unreduced bowel, now so free from pain and tenderness, is rapidly dying from obstructed circulation.

Indeed, the family doctor has not always, in such a case, the courage of his convictions, and either delays—where delay is a crime—or but half-heartedly advises a cutting operation; which suggestion the comfortable patient promptly rejects. He is no more enthusiastic for the knife than is his doctor; probably even less so.

In my previous article I described the case of an elderly lady in whom I found the strangulated gut dead, and removed thirteen inches, with immediate end-to-end reunion of the sound bowel. I then claimed that this was the largest amount ever successfully removed in America; though in a few instances in Europe more has been sacrificed with recovery—notably a case of Koeberle's, from whom 2.05 metres were excised. Since the publication of Vol. VIII., however, I have learned of an instance in which Dr. G. D. Beebe, of Chicago, removed four feet ten inches with success. Upon ascertaining this to be true, I published a statement of the facts in the New York *Medical Record* for December 5, 1891.

It is possible that in my previous article upon hernia I did not sufficiently emphasize the point regarding operation upon strangulation, that, with the rarest exceptions, it is advisable, should dead gut be found, to make an artificial anus and await a return of the patient's strength—delaying some weeks if need be—rather than to attempt a restoration of continuity, by any plan, at the time of operation for relief of strangulation. The patient is almost always in so weak a state—from postponed operation—that the *mere relief of the strangulation is all that is wise*, and the added time needed to perform either lateral anastomosis or end-to-end reunion may well turn the scale against him so that he will "die cured." On the other hand, after some weeks of vigorous alimentation, the patient will probably be so strong, in spite of the artificial anus, that the chances of recovery from the kelotomy will be much better than they would have been in the first instance.

It should clearly be understood, too, in a case of artificial anus, that, by whatsoever technique the restoration of the bowel-continuity is performed, it is never easy. No man can conscientiously attempt it who has not practised it a considerable number of times on the dog, or the human cadaver, or both. On the other hand, the general practitioner need not fear to operate for strangulation. If he is cleanly of person and patient and boils his instruments and dressings; if he makes an abundantly long cut, thereby seeing what he is about; if he always cuts until he sees the bowel, and freely relieves it where pinched; and if he treats it, when dead or doubtful, as described in the article in Vol. VIII.,—he is doing all that the most expert surgeon could do.

No one to-day advocates that relic of the dark ages, replacing the gut in the abdomen without opening the sac; for that means putting back a loop which may still be strangulated within the sac, or ruptured from the taxis, or ulcerated, dying, or dead. It is simply trusting to luck, and is bad surgery.

Neither can a conscientious man permanently replace a loop of doubtful vitality and sew up his wound. If it dies, what chance of recovery has his patient? The proper technique required under these circumstances I have already published in Vol. VIII.

Though I have just said that if the loop of intestine be dead, giving relief to strangulation and escape to fæces is commonly doing all that is wise at that time in an operative way, this remark does not apply to the much more common cases in which the bowel quickly begins to regain its normal color after cutting the constriction. Here we always, as a matter of course, devote from five to ten minutes to the necessary steps in attempting radical cure by one or another of the plans which I have either described or am about to detail. It would indeed be a pity to lose this opportunity to prevent, by good surgery, at one stroke, the possibility of another strangulation and the necessity for a truss thereafter.

Since my former article was published the technique of kelotomy for restoring continuity in a bowel badly torn, wounded, or dead, has been greatly discussed; and it cannot be said that to-day surgeons are united in opinion as to what method is best.

Were I again to meet a case such as the interesting one which I described in Vol. VIII., I should certainly not adopt the plan used then. I should to-day be able, by lateral anastomosis with plates cut from raw vegetable tissue (potato, for example), to complete the union in twenty minutes, or less in certain cases; and this saving of time would, of course, greatly improve the patient's prospects of recovery.

It is quite generally admitted, now, that statistics, so far as they can be trusted, favor lateral anastomosis as against any of the end-to-end plans, though sometimes a lack of room compels us to use one of the latter. The deadly mesenteric junction is where leakage so often occurs, following operation by the terminal methods; and from the very first the new opening is of necessity smaller than the normal, and still further to be reduced when the plastic exudate covering the line of union is changed, as finally it must be, into scar-tissue, and this undergoes the inevitable shrinkage.

The very small opening that exists during the days before sloughing carries it away with the fæces, is the objection, too, to the recently devised and most ingenious button of Dr. J. B. Murphy, which in cholecysto-enterostomy seems destined to be a brilliant success.

If *oblique* division of the bowel-ends be done, then, to be sure, the lumen is larger, but there is often a consequent bending or knuckle of the gut at that point, and the mesenteric danger remains. By any "stove-pipe" method, such as Jobert's or Robinson's, mistaking the proximal for the distal end would be fatal. And though Nothnagel's salt-test, as to direction of the peristaltic wave, seems an unsafe guide, we do not wish to start at the cæcum and handle perhaps ten or fifteen feet of bowel to make sure which end is proximal. Then, too, by any "stove-pipe" plan, if much is excised, we are met with the difficulty that the proximal end is distinctly the larger.

By lateral anastomosis, on the other hand, the operation is done at least as quickly, and it makes no difference thereby which end is proximal. The danger of leakage at the mesenteric junction with the bowel is removed; and an abundantly large incision—four inches or so, which is now always a point to be insisted upon,—permits a free canal, even if with time the new opening contracts one-half, which it will probably do. The blind ends, which theoretically might be expected to give trouble and accumulate fæces, practically do not do so, and quickly atrophy.

At the present date a majority of surgeons advocate lateral anastomosis; and, following the lead of the Germans, they have made what I believe to be a distinct backward step in laying aside all plates, rings, or other devices for aiding rapid work, and have returned to the older and certainly slower plan of suturing without such aids.

Since time is so tremendous a factor in success in bowel-work,—inasmuch as a difference of five or ten minutes with the peritoneum exposed may make all the difference between life and death,—I cannot too strongly oppose the present tendency to leisurely sewing. Speed, breathless speed, is, next to cleanliness and thoroughness, the keynote which cannot too often be sounded here.

In discussing the various mechanical means of rather recent device, I cannot but think that the best of these, for reasons purely logical, are plates with a narrow, four-inch long, opening cut from raw vegetable tissue; for instance, raw potato or turnip. These I devised and experimented with (trying also a number of other kinds of vegetable and fruit tissue) in the physiological laboratory of the College of Physicians and Surgeons, New York, during the whole winter of 1890–91, with the result that the last seventeen dogs subjected to kelotomy and the use of such plates recovered.

Upon the living human subject this material—raw vegetable tissue—has been submitted to the hardest test in Germany, where, in the summer of 1892, Dr. R. von Baracz, of Lemberg, and subsequently Dr. Richard Heigl, of Coblentz, each performed abdominal section for gastro-enterostomy, both patients recovering. Dr. Heigl, in his published comments, praises these plates (in these instances cut from raw Swedish turnip) as better than Senn's bone plates.

It is evident that if at any point the danger exists that such material might be digested and absorbed too soon, it would be in the stomach. Hence the value of these tests by the German surgeons named.

When soaked for an hour or two in warm or tepid water (not in carbolic solution, which softens it) these raw vegetable plates—I still prefer white potato—become as rigid almost as wood. This is probably due to swelling of the starch-granules; but is not accompanied by any marked change in shape of plates already cut out. After remaining for a few hours exposed to the digestive fluids of either stomach or bowel the plate begins to soften, while retaining its shape. At length it is completely digested and disappears, this occurring at a period of time varying according to what part of the alimentary canal it occupies. But always during the first ten or twelve hours at least—the time in which, most of all, we fear leakage at our anastomosis—it holds the peritoneal surfaces smoothly in contact.

In this length of time, or even half of it (if we have lightly scraped the surfaces to be apposed), we may be sure of firm agglutination. And after these hours of peril the softened plates yield to peristalsis, and quite easily cut free from their plate-sutures, taking themselves out of the way.

Contrast this with Senn's bone plates, which occasionally slide on each other and obstruct the opening, and require at least a week or so to be removed after they have ceased to be needed; which are tedious to prepare, expensive, and require multiple sizes for various contingencies; which are not to be gotten in an emergency; and which, finally, so far as the opening is concerned, are too small-sized. Whereas, on the contrary, these vegetable plates serve every purpose of Senn's, are more quickly softened and absorbed when no longer needed, may be carved in a minute, are always at hand, may be made, if desired, with a four-inch opening, and are devoid of cost.

The various catgut substitutes for plates, such as Abbe's and Davis's, are of comparatively little value, because, after a short time in the wet, warm fæces, they lose all rigidity, becoming absolutely limp. The same is true, in lesser degree, of Brokaw's segmented rubber rings filled with catgut strands. Moreover, the catgut devices swell greatly when put in any watery solution, such as semi-liquid fæces; and, as Senn alleges, have sometimes thus produced dangerous pressure at the point of ligation. The catgut rings of Abbe (described in my previous article) are no longer used by him. A number of patients have recovered under their employment, but union of peritoneal surfaces was largely due, I must think, to the row of sutures surrounding his rings wherever used.* The solid catgut (drum-snare) rings devised by Matas are not open to the same objections as the other members of that group, but they require to be boiled and otherwise specially prepared. Robinson's plates of fresh raw hide would seem to possess no advantages, and certain obvious disadvantages, when compared with the plates cut from raw potato.

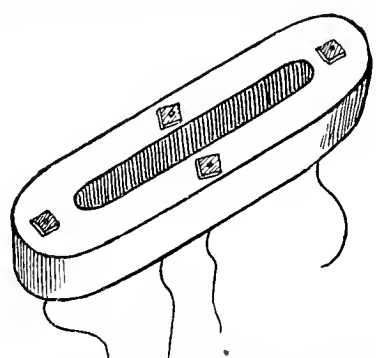

FIG. 247.—The Potato Plate Ready for Use. (Threads short and needles omitted; plate reduced about one-half in length.)

Regarding the question of safety (aside from the factor of speed) in bowel work by any method, two points are often neglected, and, as I believe, to the patient's peril.

The first is the *scraping of the peritoneum lightly*, wherever adhesion is desired. This can be done in a few seconds, and should not cause bleeding if properly performed, but simply congestion; and, because of this, a

* As a matter of fairness, I wish to state that in a few instances these rings, on being recovered forty-eight hours or so after an unfortunate demise, have been found *hard*. It is pure guess-work trying to account for such an oddity, but it would seem most likely that in these patients, the bowels being thoroughly emptied, at or before the time of operation, of their semi-liquid contents, the catgut rings were not given a free opportunity to absorb water and become soft.

more rapid and certain plastic exudate sealing the apposed peritoneal surfaces.

This matter seems to the writer hardly open to argument. Twenty cases in which rapid adhesion of *unscraped* peritoneal surfaces has occurred would prove nothing herein, when compared with one in which smooth and unscraped peritoneal surfaces did *not* become agglutinated after a prolonged contact. And such rare cases have been reported, although the surfaces were in contact many hours after being sutured.

A light scraping, as Senn first demonstrated, will render certain the formation of very firm adhesions within even three or four hours.

The second point which, it seems to the writer, is commonly neglected, although of the utmost value, is *always to give the patient, even before the anæsthetic, as large a dose of morphine by needle as is compatible with safety to his life.*

In the first place, by following this procedure, much less ether or chloroform will be needed than if no morphine be used, and the consequent liability to vomiting, with its attendant risk of tearing out or loosening sutures, etc., is hence largely avoided. Probably, too, morphine is of some little value as a prophylactic against shock from the severe operation about to be undergone. I quite agree with Dr. John B. Roberts,[1] who, in discussing operative shock, says: "The preliminary hypodermic injection of morphine and atropine, always given a quarter or a half-hour before commencing anæsthesia, probably lessens the shock, and without much doubt diminishes the tendency to vomiting after etherization has been discontinued."

In the second place, because of that morphine the bowel will be absolutely quiet, absolutely devoid of peristalsis, for hours afterward; and this is just what we need: *splinting* the intestine for a short time.

Peristalsis during these critical hours, before fibrin has sealed the spaces between our stitches, is fraught with such danger that to permit it is almost like inviting a possible leakage, by forcing out a drop, here or there, of liquid poison.

Should we refuse morphine, we cannot depend for safety upon the paralysis, however commonly present, of the loop recently subjected to operation. For, although this portion may be quiescent for some hours, yet the whole alimentary tube above will not be so! And semi-fluid fæces are being hurried along in surging currents, thrusting themselves forcibly against the newly placed barriers, whether of thread or plates.

Indeed, it is only because I also insist upon the use of morphine as stated that I think the use of plates absolutely safe without a complete row of stitches about them. During the hours while the plastic exudate from the lightly scraped peritoneum is sealing, more firmly than any sutures could seal, that wound, the intestine is as devoid of motion as if dead.

Let me here interpolate the remark that if the patient's general condition were excellent, and the abdominal cavity had not been very long opened (not otherwise), I should, as precaution upon precaution, sew once entirely around the plates a running Lembert, or some similar stitch, such as that elsewhere illustrated (see Fig. 248). And because of the smooth tension made possible by the plates, this sewing could be completed quite a little sooner, as well as more safely, than otherwise. In dealing with the lower half of the ileum, the danger of an occasional complete penetration with the needle is a very real one, save in expert hands—so very thin-walled is this part of the intestine.

To return to the question of a *morphine-splint:* the writer is not ignorant of the views upon peritonitis held by Lawson Tait and many other surgeons. The writer acknowledges the wisdom of its treatment, or better, prevention, by saline laxatives; but submits that here (as distinguished from ovarian or uterine surgery) exists an indication of the strongest kind for the use of morphine. And in the great majority of instances of this particular class of abdominal work, that indication outweighs, in his judgment, the arguments on the other side. Furthermore, it must be distinctly understood that the writer would not at all approve of continuing for an indefinite period to exhibit morphine, following bowel and stomach operations. When from ten to twelve hours have elapsed, then we can feel assured that firm agglutination has occurred between our lightly denuded peritoneal surfaces; an adhesion so firm as almost to tear elsewhere rather than yield at that spot. And now, the liability, or even the possibility, of leakage being practically past, we should, if there be some tendency, then or later, to abdominal distention, from this period *post operationem*, give hourly, small doses of saline laxatives, and perhaps also a glycerine enema. Under this line of treatment the effect of the morphine upon intestinal peristalsis is, within a few hours, overcome; and usually quite readily so.

And what, now, becomes of the five-inch plates of potato or turnip within the gut?

After twenty-four hours, or, if high in the intestinal canal, after perhaps even a somewhat lesser period of exposure to the heat and digestive fluids therein, the plates will readily yield to the waves of peristalsis, first permitting the freest passage of fæces through the four-inch lumen, and presently cutting out at the plate-stitches because of extreme softening; and they will be swept away. Their four stitches, if, as seems preferable, of catgut rather than silk, are soon after absorbed and also disappear.

Let me now describe in some detail a method of lateral

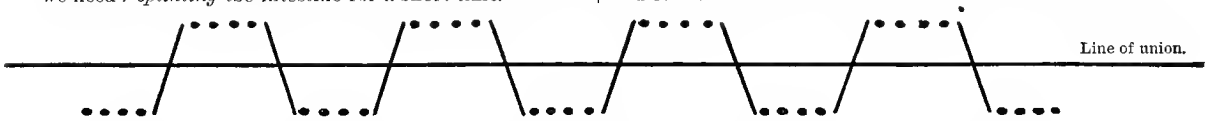

FIG. 248.

anastomosis with plates, as practised by me since the winter of 1890–91 (in entero-enterostomy only). In such operations—not very rarely needed, following, for instance, dead gut from a strangulated hernia, or resulting from tearing into the alimentary canal during separation of old adhesions in major gynecology—the technique about to be described possesses two advantages over any other, with plates or without them. These are: (1) Opportunity to test by the water-test the perfection of the line of suturing. (2) Entire avoidance of possible infection of the line of intended adhesion by repeated accidental dragging out, necessitating tucking back of the cut bowel-edges, which are none too thoroughly disinfected at the best.

Regarding the first point (the hydrostatic test), it is with surprise that I have noted how little it has received attention. If the operator means to depend solely upon suturing for securing union, one would suppose that from a half minute to a minute more spent in proving such stitches evenly and properly tight would be anything but wasted. Indeed in the bladder this is commonly done.

The error lies in closing the bowel-ends *first*, and *then* making the lateral anastomosis, with its surrounding lines of suturing (or plates). Such technique of course prevents the water-test. If instead, as suggested by me, these steps be *reversed*, then by running a stream of warm water into one gut-end, through the new lateral opening, and out of the other gut-end, how easy it is, in a moment, to notice a point of leakage and to correct it by an additional stitch! The tapes or clamps, always applied a few inches away, of course prevent the water from taking another path than that desired. And *then* the bowel-ends are to be inverted and closed, instead of this being made the first step of the operation.

And how much more pleasant, so to speak, for the

patient, to have a stream of leakage discovered at this time rather than subsequently upon the autopsy-table!

As to the second point in technique mentioned, let me quote from a recent article by Dr. Robert F. Weir:[1] In speaking of anastomosis he says:

"I had already called attention . . . to the tendency of the opposed intestinal incisions to slip out beyond the rings. This also occurs with Senn's plates, and, in fact, is common to all of these contrivances, so that special care in their use is demanded, and often the escaping portion requires to be tucked in between the plates more than once before the restraining outside sutures are finally inserted."

Had Dr. Weir used the method about to be described, he would not have had this complaint—and it is a just one—to make, regarding the usual methods either of suturing or of using plates. By the writer's plan, any and all sewing to be done about the new opening is completed *before* that opening is made, and for just the reason given.

Preparation of Plates.—These are cut one-third of an inch in thickness, and on an average five inches, or nearly, in length. Their width is not great, in order that they may slip easily into the bowel. At first I made them too wide. A very narrow slit is all that we need. The powerful circular muscles cause the cut bowel-edges in the slit to retract so that they do not touch each other, and the prompt infection of these edges by fæces prevents the likelihood of their adhering even if they did touch. The slit should be nearly or quite four inches in length. Of course this length is an added safety (immediate as well as remote), because the freer the passage of fæces when that begins, the less the strain on the integrity of the line of union.

Each plate is armed with four coarse catgut threads, not over nine inches long, to avoid tangling. The threads have a large knot, and before penetrating the plate we sew through a scrap of rubber cut from a drainage-tube, or, lacking this, a minute bit of cloth; this to avoid cutting through. If no running line of sutures about the plate is contemplated, it will be best to use *six* instead of four threads in each plate. Use a round, straight sewing-needle, the eye of which (to avoid accidental unthreading) should be a close fit for the catgut. The needles should all have their points buried in bits of potato, each about the size of a pea. If time permits, immerse the plates for a half hour in warm water, to make them more rigid and hard.

Method of Using the Plates.—Assume that the tapes or clamps are applied, and the bowel properly cleansed out by irrigation. Now:

(1*a*) Seize a needle with the needle-holder so that it shall be in the long axis of the holder. Begin with the one marked *A* in the accompanying diagram (Fig. 249). Pass the needle several inches (about seven, in operations upon the small intestine) into one of the open gut-ends, and when the place is reached at which, in the judgment of the operator, it should come through, detach the bit of potato from its point with the fingers, seizing it from without, and then pass the needle through and out. The little piece of potato will take care of itself, dropping to the bottom of the bowel; it is insignificant. The spot at which the end sutures, *A* and *D*, should escape, is one directly opposite the mesenteric attachment; that is, as far as possible from the mesentery. Now (after *A*) pass needles *B* and *C* in the same way. After each thread is passed, it should be held by an assistant tense against the wall of the gut on the side where it belongs, and the next needle should carefully run along the opposite wall; this to avoid tangled threads. Pull lightly on threads *A*, *B*, and *C*, while pushing the plate from behind, drawing it thereby into place within the intestine. Push rather than pull, to avoid oblique tension on the threads and possible cutting of the plate. Next pass *D*, and draw it also taut.

Go through the same steps with the other plate and the other gut-end. Always leave at least a full inch and a half between the plate-end and the gut end, in each instance.

(1*b*) The following alternate method of introducing the plate and its threads is, so far as the suggestion of the shorter needles is concerned, due to Dr. H. M. Hall, of Seattle, Washington. The plate is to be armed with four (or six) short, straight, round (so-called gynecological) needles, only one-half to two-thirds of an inch long. Their threads need not exceed four inches in length. (In other respects they are prepared as in the other plan.) These needles are inserted into the plate at their proper places, and their points made to penetrate just to the thickness of the plate, but no further. (These preparations are, of course, made before the operation begins.) The plate thus prepared is laid, needle-hilts downward, upon a thin, long strip of hard wood, as wide as the plates—a piece of cigar-box, for instance,—and both are inserted together a sufficient distance into the intestine, from its open end. By placing the four short plate-threads each on its own side of the wooden strip, tangling during the insertion is avoided. It is now the work

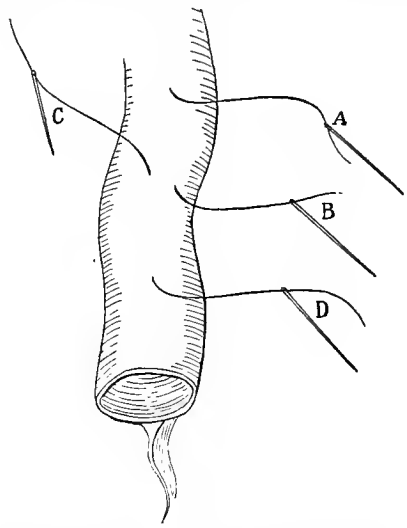

FIG. 249.—A plate in place and ready to tie to its fellow.

of but a moment to press upon the bowel overlying the plate, and thereby force the needles through at exactly the right places. Their points are seized by the needle-holder, and each is drawn through until its thread is tense.

By this technique, which I prefer to the other, both plates may be inserted and their threads tied in less than two minutes. The former technique would be necessary where only ordinary needles are procurable, *i.e.*, in emergency work.

(2) Wipe off the threads with a cloth wet in some antiseptic solution. Of course, this is not essential, but is a safeguard.

(3) Scrape lightly but thoroughly with a scalpel the surfaces to be coaptated; this also includes the ends to be inverted.

(4) Tie the four anchor (plate) threads each to its appropriate fellow, being careful to draw snugly but not to make extreme pressure. Tie first the threads on the lower (under) side of the seat of operation. Sloughing is of course possible if no care is used; though because of rapid softening of the plates, inside of twenty-four hours, it is less a danger even in careless hands than if bone-plates were used.

Experience proves that it is of little moment in which directions the open ends are pointed, before this ligation of the threads; that is, whether in opposite directions or not.

(5) Take one square Lembert stitch at the plate-edges, opposite to and concealing each of the four (or six) plate-stitches. This is precautionary. In the event of a drop of pus forming where a plate-stitch penetrates the gut (infection by capillarity), that pus, like any other fluid,

would move in the direction of least resistance, and, the softened plates not opposing, would be obliged, by this square stitch, to re-enter the intestines at the cut edge.

As an alternate choice—and perhaps preferably to such interrupted stitches—we may, as a matter of convenience, begin the entire operation by a straight, running line of suture five inches long, between the loops to be joined, and about one-fourth inch from their mesenteric border. This line may, if desired, be continued and carried completely around the plates, after these have been tied together. The stitches are rapidly inserted, being no more than three to the inch, and are preferably of the kind illustrated in Fig. 248. The surfaces are smoothly coaptated, and sloughing, from over-tension, is hardly possible; because the pressure from any stich of this continuous thread is not met by that of an opponent across the line of union.

Just as in suturing without plates, about the opening, great care should here be exercised lest the surgeon sew too deeply and penetrate into the bowel. As has been previously remarked, the smooth, though moderate, tension about the plate-edges permits very rapid and accurate sewing.

If the patient were in real and immediate jeopardy, I would advise not stopping for sutures at all; but, as the end of the bowel technique, to wrap

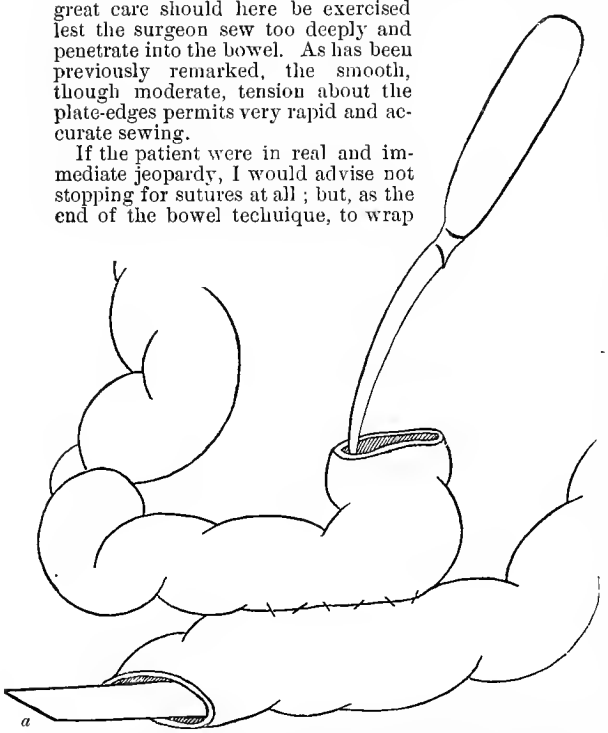

FIG. 250.—The suturing about the plates is completed; the anastomotic opening is being made; in short lines the row of sutures is indicated roughly; *a*, block of wood, to cut against. (When properly tightened, the sutures cannot easily be seen, of course.) Straight scissors, with one sharp point, should be substituted for the knife in this illustration.

around the plates at their line of union a long strip cut from the omental edge. A preliminary cobbler's ligature applied to the omentum will avoid loss of blood here. This, by actual time measurement, may be done in one minute. Such an omental strip is shown by Senn to be almost sure to live, though completely detached, for it becomes firmly adherent where it rests, and is a decided additional safeguard against possible leakage, with consequent infection.

(6) Run into one open gut-end a thin strip of wood as wide as the potato-plate (*a*, in Fig. 250). This is to cut against.

(7) Now we make our opening through the opposed and sealed gut-walls. I strongly advise for this purpose straight scissors, with, as usual, one blade sharp-pointed, instead of the bistoury indicated in the illustration (Fig. 250). If desired, by a little trouble, the bowel-end may be so held as to render the line of incision visible throughout its whole length; but this is hardly worth while, as with the scissors one can very easily feel, before cutting, the slit in the plate, and thus be exactly guided. We should make as long an anastomotic opening as the plates will allow. The strip of wood opposite, which has prevented cutting too deeply, should now be removed.

Should bleeding follow, of more than trivial degree, it could easily be controlled by forceps. As stated, the incision is open to inspection—from either end—with a little care. Also, the potato is elastic enough to permit, without harm, a temporary widening of the slit by any blunt means, for greater ease in seizing a vessel.

However, annoying bleeding is very unlikely to happen, both because the point at which the bowel is divided is that farthest from the mesentery, and, therefore, where the vessels are smallest; and, also, for the reason that the moderate pressure of the plates would tend to check it.

(8) Irrigate, under very gentle hydrostatic pressure, closing the outlet end with finger and thumb for a few moments. The line of suture, or union, should not leak, if contact is properly made.

(9) Invert and close the ends, each with one running line of suture, as in Fig. 248. The free end is seized with dressing-forceps and turned in until the plate is felt. The forceps holds it thus inverted while the stitches are placed. The long intussusceptum, far from being the danger that was once feared, proves a decided protection against leakage. A few needles, temporarily thrust through the intussusceptum transversely, prove of aid in preventing the rolling out of a part of the end during sewing.

(10) Take a stitch or two between the blind ends and the bowel, against which each should rest, first scraping lightly. This sewing prevents possible forcing of another loop into this angle, with resultant undue tension on the stitches at the plate-ends; an accident which led to leakage in one of my first experiments on dogs. It is also a safeguard against intussusception into the new opening, which has been observed by one worker in this field (Robinson). Of course, this point in technique is as applicable to lateral anastomosis without plates as to that with them.

Finally, of course, we remove the clamps or tapes from the bowel on either side of the region just subjected to surgical treatment.

For the sake of clearness, ten successive steps in performing the operation have been numbered and itemized; but it will be noted that half of these are not peculiar to this, or any other plate method, but are just as advisable when suturing alone, without such aids, is attempted.

I know of no briefer, no safer plan. It is my hope that the points herein discussed, and which the reader may not heretofore have put in practice, will be accorded an unbiased trial. They are the fruit of a number of years of work in this line; and the conclusions have not been drawn without time for consideration.

In discussing anew the subject of radical cure of rupture, the writer wishes to call attention to the appalling frequency of hernia, as marking the importance of the subject, and therefore demanding of every medical man his most earnest study.

The tables of Dr. Baxter show that not less than *three million* people in these United States are so afflicted; and the recent and thorough work of Dr. H. O. Marcy, in which these figures are quoted, does not deem them excessive.

Malgaigne estimated that in France one in every thirteen males, and one in every fifty-two females, are ruptured; including both sexes, one in every twenty.

Since my former article was published there has been a most striking change in the mental attitude of the surgical world—due to published statistics—upon the question *when to operate upon hernia which is not strangulated.*

It is not too radical a statement to say that, to-day, most surgeons advocate operation for radical cure *simply because a patient has a hernia.*

If this is true, it must be for the reason that surgeons not only think that radical cure is now regularly to be expected following operation for that purpose, and that

failures are indeed few; but also such advice must mean that, whereas once a patient herein jeopardized his life, now, from thorough asepsis, the operation has become practically free from all danger; as much so as amputating a finger, for instance.

The following figures will put the reader in position to judge for himself upon this matter:

Bassini has published 251 cases, with but 1 death, from pneumonia, when the wound had aseptically healed. Svennsen and Erdman, at the Sabbatsberg Hospital, 200 operations, no deaths. Lucas-Championnière had a single death among his 266 cases; cause not stated. Kocher, 119 operations, 1 death from pulmonary embolism on the fifteenth day after the operation, when the wound was completely healed. Macewen has lost 1 patient, from scarlet fever, out of his 98. Roswell Park, 85 cases, no deaths. Halsted, 83, no deaths.

It must ever be borne in mind, however, that such safety as this implies *absolute surgical cleanliness*, and this is no slight acquirement. This is a true cœliotomy, for by any and all modern methods of attempting radical cure of hernia the peritoneal cavity is opened in order to ascertain accurately whether the sac is empty or not. Let no man dare attempt it until he has made sure by lesser operations, in safer regions, that he can always command asepsis; that wounds of his own making shall regularly heal without suppuration.

Regarding the question of success in effecting radical cure, Bassini reports recurrences among but 5 patients in 251 cases of unincarcerated inguinal hernia; although—be it remembered—the period over which many of these cures extend is far too short to permit of our considering this report a final one.

In one of his recurrences Bassini had not removed the sac as usual. In another he trusted entirely to catgut sutures. In two others there was not strictly a recurrence, but simply an abnormal bulging at that part of the abdomen.

Kocher records 76 cases with but 2 recurrences; covering a period of from four and a half years down to less than a year (in a few cases).

Halsted has recently told me that from the time in 1889 when he began his present technique, until now, in 1893, he has had no recurrences among his 83 cases.

It would be a waste of time to multiply figures here. The methods which are now generally regarded as most reliable are of such recent introduction that the true results as to radical cures—those covering periods of not less than three, and better, five years as a test—are not yet obtainable save in a very limited number of cases.

However, it is extremely instructive to learn what *not* to do; and a study by Dr. W. T. Bull,* of a series of forty cases, inspected at periods varying from a few months to six years, is of great value herein; and his frankness in reporting undesirable methods, which he doubtless no longer uses, is a virtue all too rare.

He says: "Twenty of this number had been operated upon by excision and ligation of the sac; the remaining twenty had excision and ligation of the sac, together with suture of the pillars of the external abdominal ring. . . . By both methods, in all varieties, there were sixty per cent. of cures, and forty per cent. of failures."

In a second paper he states that only about half his wounds healed primarily; slow-healing drainage-openings being generally the cause of this. His drains were of rubber, usually. His catgut sutures were prepared by saturating them with Kocher's oil of juniper plan.

In this latter paper the importance, by any method, of obliterating the sac is emphasized. He states that *every* case operated upon by him after the method of Heaton—with injection of a solution of white-oak bark into the inguinal canal—has now relapsed!

Dr. Bull insists, as do Macewen and Lucas-Championnière, on the use of a truss "from the time the patient leaves his bed."

In this respect he differs from Bassini's customary practice, from McBurney, from Wölfler, and, in most cases, from Kocher. I cannot help feeling, however, that it is the part of wisdom to give the newly healed wall a light support for a few weeks by a truss (unless, indeed, the patient has been kept about six weeks in bed). If this were permanently to be worn, however, as a necessity, that would imply no true and radical cure, and should not properly be classed as such.

* Read before the New York State Medical Association, 1889.

In Vol. III. the reader will find discussed certain methods—mostly antiquated—of attempting radical cure. In my former article, in Vol. VIII., are yet other studies upon this subject, giving especially the plans advocated by Drs. Czerny, Banks, Nussbaum, Sewell, Riesel, Barker, Ball, Macewen, and McBurney. Since the final volume of the HANDBOOK appeared, various additional methods have attained prominence. These from their originality, or else their intrinsic value, deserve a permanent record, and will presently be discussed here.

It is noteworthy that two points in the technique of operation upon the inguinal canal have of late years received especial care.

The first of these has reference to strengthening the weak rear-wall of that canal, which, for an inch or so to the inner side of the deep abdominal ring, is composed of nothing more resisting than transversalis fascia and peritoneum. Obliteration of the sac, alone or combined with closing the external (superficial) abdominal ring by sutures, will still leave this a weak spot. And if once the bowel *begins* to re-enter the canal, inevitably the wedge principle will at length permit of a complete return of the hernia. Therefore it is that most surgeons to-day so carefully sew together the deep parts, hoping to prevent, by a tight, deep ring, and a strong, musculo-aponeurotic rear wall of the canal, the least admission of the thin end of the wedge.

The second of these points just referred to is the fact that an element of weakness in our operations is the presence of the spermatic cord running through the canal. If we could prevent this, then the canal could be solidly and completely closed against the invading bowel. In the middle ages, as Kocher has recently reminded us, surgeons used to castrate their patients, and remove the cord, as a simple means of solving this problem. Literally, that was cutting the Gordian knot with a vengeance! and led to a popular outcry against such surgery. Of late, certain operators have insisted upon the importance of this principle; and, without castrating, have nevertheless succeeded by various plans in permanently emptying the inguinal canal of the spermatic cord. Drs. Halsted, Fowler, Postempski, Wölfler, and Frank, are instances in point.

Among so confusingly long an array of methods the reader may wish to know which are at this time regarded by the profession with most favor.

I think I am safe in replying that to-day Bassini's method stands first in popularity among surgeons, and Macewen's second. Others are regarded as either more complicated, or as yielding a smaller percentage of true and permanent cures.

Bassini's Method.—This was first described by Dr. Eduard Bassini, of Padua, at the Congress of Italian Surgeons held in March, 1888. He reported at that time two hundred and sixteen cases. The following, which I have carefully compared with his own more recent article,* is taken very largely from Dr. S. E. Milliken's clear description.

Operation.—An incision is made, beginning at the spine of the pubis, and extending upward and outward. The upper extremity should be about two inches internal to the anterior superior spine of the ilium; everything is divided down to the aponeurosis of the external oblique. The latter is incised over a grooved director, passed into the external abdominal ring, superficial to the hernial sac and cord structures, and then running outward even a little beyond the deep ring. To expose this ring properly, the aponeurosis should be cut for about two or two and one-half inches. The upper flap is now freed from the

* Archiv. f. klinische Chir., Berlin, 1890, vol. xl.

underlying structures and reflected toward the median line until the conjoined tendon, composed of the internal oblique and transversalis muscles, is brought well into view. The lower flap or segment of the anterior wall of the inguinal canal is next dissected from its underlying fascia, until the shelving edge of Poupart's ligament is exposed. These flaps being held back by retractors, the next point of technique is to hook up with the index-finger the cord structures as they pass over the spine of the pubis, and lift them and the hernia out of their bed. This blunt dissection should be continued until you have reached the deep ring. The hernial sac, without reducing its contents, should now be isolated; this is best done by dividing the overlying structures on a grooved director until you have exposed the bluish-gray thickened membrane over a small area. This coat is raised with a small pair of rat-toothed forceps, that the hernial contents may not be injured when the opening is made. The entrance into the peritoneal pouch should be manifested by the escape of a small amount of serum, unless it be an incarcerated or strangulated hernia, when the fluid may be tinged with blood. The contents having been examined, all adhesions that may exist are tied off with fine catgut. Large masses of omentum should be ligatured, not necessarily at the most distal point, but

Fig. 251.—First Step.

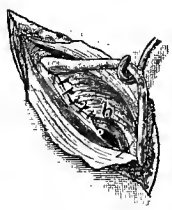

Fig. 252.—Second Step.

Fig. 253.—Third Step.

Bassini's Method of Operation for the Radical Cure of Hernia.

where the greatest constriction exists, and it is advisable to use the transfixion method. Occasionally it occurs that the obstacle to reduction is a fibrous constriction, situated within the deep ring. That is, however, easily detected at this stage of the operation, and can be divided without danger by incising upward. Returning to the treatment of the sac, it must be completely separated from the cord and other adherent tissues, to a point *well within the deep ring*, and a moderate amount of traction made uniformly at all points, which is best accomplished by a series of artery forceps held by an assistant. (The blunt dissection of the sac from the cord and other structures is best begun at its neck.)

Ligation of the sac with catgut is now done, also, by the transfixion method, having first twisted it at its neck. The sac is excised, leaving the pedicle about a fifth of an inch (one-half centimetre) in length, which immediately retracts into the abdominal cavity. If the hernia is very large, and thus the neck and opening of the sac are broad, Bassini applies, besides the ligature mentioned, a glover's suture, for security's sake. When a congenital hernia exists, the sac should be cut off one inch above the testis. The reforming of the tunica vaginalis is of no importance, and the prevention of hydrocele will thus be attained. This completes the first step of the operation (Fig. 251).

Second Step.—The upper and lower flaps, composed of the segments of the aponeurosis of the external oblique, being well retracted by sharp hooks, the cord structure held out of the operative field by a blunt hook or the finger of an assistant (if necessary we may lift the testicle out of the scrotum in doing this), the conjoined tendon of internal oblique and transversalis muscles, on the upper side, is now united to the shelving edge of Poupart's ligament by a series of interrupted chromicized catgut or kangaroo-tendon sutures. Bassini prefers silk sutures. The Macewen blunt-pointed needle accomplishes this admirably, but any curved needle will do. The needle, when passed through Poupart's ligament, must not include more than one-quarter of an inch of tissue from the edge. The relaxed posterior wall of the canal, composed of the transversalis fascia, should be included in the upper grasp of the needle, along with the conjoined tendon. From four to six sutures, inserted in this way, will be sufficient to unite firmly the musculo-tendinous structures, forming a new posterior wall for the canal. In this reconstruction care must be taken not to constrict the tissues of the cord. The first two sutures, close to the pubes, include also the border of the rectus muscle.

All of these stitches should be made to include a large amount, say an inch (two to three centimetres), of the internal oblique and transversalis muscles (Fig. 252).

Third Step.—The formation of the anterior wall of the canal is accomplished by suturing the recently divided external oblique aponeurosis, continuously, with fine catgut (Bassini uses silk), throughout its entire length (Fig. 253). This re-establishes the valve-like condition of the inguinal canal. Finally, the skin wound is closed with interrupted sutures after the insertion of a small glass drainage-tube, from two to two and one-half inches long (Bassini commonly does not use drainage) into the lower angle of the wound, and the following dressing is applied:

Iodoform powder (or what is preferable, fine crystals) should be spread along the line of suture and around the drainage-tube; on this a strip of Lister protective or rubber tissue, two inches wide and long enough to overlap one inch at the ends, a perforation being made for the drainage-tube; moist iodoform gauze, six layers thick and sufficiently long and broad to overlap the wound two inches on all sides, also perforated for the drainage-tube; next, a larger compress of moist sublimated gauze is placed over the upper part of the wound and held in position by a two-inch strip of surgeons' rubber adhesive plaster, extending almost entirely around the pelvis. An intervening layer of rubber tissue should be used to prevent infection of the wound from the plaster. Over the drainage-tube is placed sublimated gauze, very loosely distributed; next, cotton, and lastly it should be covered by rubber tissue, one foot square, which is perforated for the penis and held in position by a spica bandage. The advantages of having the above dressing are several: First, infection from without is prevented by the rubber tissue, which is most external, and by the small strip which is in immediate contact with the skin. By means of the adhesive plaster alone can perfect retention of the deeper dressing be accomplished. However, the most important point in this detailed dressing is the arrangement of the drainage-tube, which should be removed at the end of thirty-six or forty-eight hours by simply taking off the external dressing and not disturbing that which is in immediate contact with the wound. After the removal of the drain the point of exit should be well dusted with iodoform, covered with loose sublimated gauze, and a new protective dressing applied. Where animal sutures have been employed the wound should heal under one dressing, even in cases of strangulation. Perhaps two to three weeks in bed would be the average duration. Some have been allowed to get up as early as on the tenth day. No truss is advised.*

Method of Dr. William S. Halsted.[2]—This plan agrees in most essential respects with that of Bassini, but in addition so deals with the spermatic cord as to remove it—by a plan presently to be detailed—permanently from the inguinal canal, at the same time reducing its size. Consequently there is made—1, a new posterior wall to the now obliterated canal; 2, a tighter deep ring, the

* The writer, while preferring Bassini's technique in most respects, would suggest as a plan worth trying, the complete and permanent emptying of the inguinal canal by a method which he has not seen heretofore described. This consists in drawing the testicle, by its cord, out of the scrotum and then placing both cord and testis in the loose cellular tissue behind the inguinal canal, where they are to remain. Over them the conjoined tendon is sewn to Poupart's ligament as just described, etc. The advantages of having no canal and no inguinal rings is obvious, and true castration is avoided.

latter in a new situation; and 3, a much smaller spermatic cord.

Dr. Halsted published his method in the autumn of 1889, eight or nine months before that of Bassini appeared in print; although the latter surgeon, as heretofore stated, read a paper upon his method, in Italy, in 1888. Both began work upon a clear and definite new principle in hernia operations—Halsted upon two new principles—at about the same time. The priority is commonly, under such circumstances, given to the paper first appearing in print; and should therefore rest with Halsted.

The following is his description of this plan:

1. The incision begins at the superficial abdominal ring, and ends one inch or less (less than one inch in children) to the inner side of the anterior superior spine of the ilium, on an imaginary line connecting the anterior superior spines of the ilia. Throughout the entire length of the incision everything superficial to the peritoneum is cut through.

2. The vas deferens, with its vessels, is carefully isolated up to the outer termination of the incision, and held aside.

3. The sac is opened and dissected from the tissues which envelop it.

4. The abdominal cavity is closed by quilted sutures passed through the peritoneum at a level higher by one and a half to two inches, than that of the so-called neck of the sac.

5. The vas deferens and its vessels are transplanted to the upper, outer, angle of the wound. Before doing this, all the superfluous veins of the cord (all of them save one or two) are excised; thereby reducing the size of the cord, perhaps three-fourths. Consequently the new deep ring will be much smaller than otherwise—an evident advantage.

6. Interrupted, strong silk sutures, passed so as to include everything between the skin and the peritoneum, are used to close the deeper portion of the wound, which is sewed from the crest of the pubes to the upper, outer, angle of the incision. The cord now lies superficial to these sutures, and emerges through the abdominal muscles about one inch to the inner side of the anterior superior spine of the ilium.

7. The skin is united over the cord by interrupted stitches of very fine silk. These stitches do not perforate the skin, and when tied they become buried. They are taken from the under side of the skin, and made to include only its deep layers—the layers which are not occupied by sebaceous follicles; this to avoid possibility of suppuration by stitch-infection.

Dr. Halsted has for more than two years sewed most of his wounds in this way. The method was suggested to him by his experiments on dogs. He thinks that it is very difficult, and perhaps impossible, to disinfect the skin of a dog, and believes that pyogenic organisms may occasionally be present in the sebaceous follicles of the skin. At any rate, he had repeatedly observed pus in the suture-holes of the perforating skin-stitches, and could not with any certainty secure primary union of the skin-wounds of dogs until he had resorted to this subcutaneous method of sewing the skin.

Dr. Halsted states, in this connection, that whether or not it is possible or easy to disinfect absolutely the human skin, he had been much impressed with the fact that skin-sutures not infrequently suppurate, even in wounds sewed by the most careful surgeons in this country and abroad. He has thought it advisable, therefore, to test for a time the subcutaneous, buried skin suture.

8. One or two small, short, gauze plugs are used as wound drains.

The After-treatment.—The gauze plugs are removed at the first subsequent dressing — usually at about the seventh day. The patients are allowed to walk about on the twenty-first day.

A few cases have suppurated. These were laid wide open at once, and the stitches divided. Should the hernia return in these cases, it could not, of course, be counted against this method. In one instance of this nature, after the wound had been freely opened again, urine at length discharged for a time by this route; showing that one or more of the innermost stitches had pierced the bladder-wall—a most instructive case.

It will be observed that whereas Bassini uses three rows of sutures,—sewing the external oblique aponeurosis as a layer by itself,—Halsted has but two rows, including every structure between the peritoneum and skin in his first, or deep line of stitches.

The object of making the new deep ring further outward than before is in order that the vas deferens may pass through broad, raw surfaces, where the muscles are thick, and be thereby snugly embraced in its new situation.

Method of Dr. J. Lucas-Championnière.[3]—1. It is necessary to remove absolutely the sac by a ligature at the highest possible point, leaving not even the slightest infundibulum in the peritoneum opposite the deep ring. To accomplish this we must dissect up the peritoneum wall above the neck of the sac.

2. In the second place we should oppose to the return of the hernia a heavy, firm cicatrix, the result of the very free dissection to expose the peritoneum beyond the uttermost part of the neck of the sac. The whole length of the inguinal canal is, of course, split open in order to do this. The larger the operation—the more extensive the dissection,—the firmer this scar will be. These deep parts are sewn together by deep sutures. (No more exact statement than this is given as to *where* the stitches are placed.)

3. It is important, where omentum is present in the sac, to treat it boldly. In this respect the author claims that he has done what no surgeons have ever done before him. He pulls out of the abdomen, using "energetic effort," the omentum, when this has been a part of the hernial protrusion, and ties off and cuts away all he can. The consequence of this is to increase the empty space within the abdomen, and to remove from the inguinal region any remaining part of the omentum. In both respects this is desirable, and the omentum no longer plays its customary rôle in provoking a relapse.

"If I consider my method of radical cure superior to all others which I have studied, it is because I believe that other surgeons have not taken the care to obey all of these three fundamental rules. . . .

"The most interesting characteristic of the operations which have given the best results is the presence, subsequently to the operation, of a cord of cicatrix, voluminous and hard, extending from the scrotum up into the abdomen, along the region formerly occupied by the hernia. . . The cicatrices really powerful, truly solid, are those made not by a suppurative process but by primary intention."

In the sewing he uses buried sutures: not to make a reunion of the pillars, in the proper sense of that word, but to fuse together and solidify all the deep soft parts resulting from the free dissection. To do this, he uses stout catgut. Sometimes the same thread, after having been tied, is repassed and its ends are finally tied together after having been made to surround a fresh portion of the soft parts.

These sutures may be placed either in single or double tier, from one end of the wound to the other. The barrier is completed by suturing, over these deep parts, those more superficial, *i.e.*, the cellular tissues situated superficially to the muscular wall. This suture is always made with strong catgut, tying invariably three times, against slipping.

An interesting point in the technique is that in those cases in which the anterior aponeurotic wall of the canal seems quite lax, after removing the sac, the author *overlaps* the lips of the cut external oblique aponeurosis, sewing them with the deeper parts, together in this position, and thereby making the canal a tighter one.

Fig. 254 shows his method of tying off the sac. He insists, repeatedly, upon this chain-method. (To the writer of this review this device seems to possess no advantages over the more simple and easily applied "purse-string" or "tobacco-pouch" suture described by Gerster,

and mentioned by me in the article on hernia in Vol. VIII. Furthermore, by the latter plan, the stump of the sac is not entirely cut off from its blood-supply, which is certainly a point worth considering.)

"Among all known ways of operating for radical cure two only seem to me more interesting than the rest, viz., those of MacEven* and of Bassini. I do not much believe in the efficacy of the folding up of the sac, thereby constituting a kind of stopper of defence to the hernial region, as MacEven teaches. But, to accomplish his procedure, it is absolutely necessary to carry the dissection of the sac very high, even into the belly; and in this his procedure resembles mine. One is assured thereby that, at least, because of such high dissection, the sac will be completely abolished, and the cicatrix due to the fusion of the freshened surfaces will be both large and long.

"As for the procedure of Bassini, I do not attach much importance to the reconstruction of the inguinal canal which he thinks to make around the cord. But to

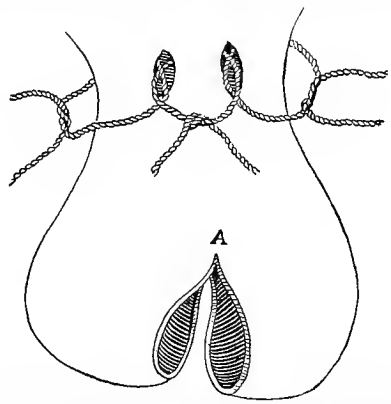

FIG. 254.—Method of Lucas-Championnière in Tying off the Hernial Sac. *A* represents the incision made for the purpose of ascertaining whether the sac is empty or not.

accomplish that end he opens freely that canal, in front and behind, and carries high his dissection of the serous sac. Necessarily, then, he will obtain a result analogous to that which I recommend—a free and thorough sac-removal and a very big cicatrix. That is the reason of his success."

Dr. Lucas-Championnière claims 266 operations upon hernia, of which 221 were in men. He states that he has had only one opportunity to operate a second time upon one of his own cases.

A propos of his radical teaching with reference to thorough excision of omentum forming a part of the hernia (quoted above), it is well to appreciate and guard against dangers due to defective technique in carrying out this procedure. Dr. W. T. Bull[4] has classified these under three heads, as follows:

1. Bleeding from inefficient ligature.
2. Damage to neighboring intestine, which may be included in a carelessly applied ligature. Such a nipping lasting only fifteen minutes before its discovery and correction, has in one published instance led to a slough, perforative ulceration, and death.
3. Inflammation and abscess of the omental stump: of course to be avoided by the strictest asepsis, and sterility of the ligature-material, of whatsoever kind selected.

As to the first of these three points, Lucas-Championnière advises, just as in dealing with the sac, his chain-ligature (see Fig. 254). Bull ligates in sections, no one of which is of as great volume as the finger. It is as well, as an additional safeguard, to tie any large vessels seen on the face of the omental stump. The latter, with but *small* masses embraced in the loops of ligature, may safely be cut much nearer to the point of constriction than otherwise; and thus less dead tissue would be left to decompose.

Method of Drs. Weir and Trendelenburg.—These surgeons, at nearly the same time, attempted radical cure by the device of opposing the return of the hernia (after tying off and cutting away the sac) by placing in the inguinal canal a plate of fresh bone. It would probably be a mistake to suppose that either surgeon regards the plan favorably to-day. Indeed, Dr. Weir quite recently spoke to me of it as having been merely tentative. He used it in two cases; in one the operation was a failure, the bone having shortly to be removed; in the other the result was unknown. Dr. Weir[5] used a piece cut from the scapula of a recently killed dog. A semicircular disk was cut out of this plate at its upper edge, to avoid pressure here upon the cord running over it. Several small holes were also punched in the plate, which was then disinfected, placed in the wound, and covered up.

I mention this method simply as standing for a principle—that of opposing to the return of the bowel some resisting solid mass filling, and yet foreign to, the inguinal canal. A very old method of attempting this is to plug the canal with the patient's testicle of that side, which has been forced up in place and held there by sutures outside, or by prolonged pressure, inducing adhesive exudation. Another of these devices was the introduction of a gelatine cylinder covered with isinglass (Belmas). The open treatment of the canal during the seventeenth and eighteenth centuries, permitting it to become filled by organic material—granulation tissue—of course comes under the same head, as does also the implantation therein of a skin-flap (Dzondi), or of the invaginated scrotum (Gerdy). This principle is not now approved by those best qualified by experience to decide, and certainly the percentage of recurrences observed after this mode of operating is not encouraging.

Method of Dr. Theodor Kocher.[6]—In describing this I have used, in the main, his own language. The skin and superficial fascia are divided over the inguinal canal, and laterally outward, in the direction of Poupart's ligament (Fig. 255). At the superficial ring the cord and sac are exposed. By lifting these toward the light the border of even a very thin hernial sac can be recognized. This is then carefully dissected and isolated from the structures of the cord until it can be strongly drawn down and its pedicle exposed. (Kocher does not mention it, but of course the sac is opened, for obvious reasons.)

The index-finger of the left hand is now introduced into the inguinal canal, and laterally from the deep inguinal ring a small opening is made through the aponeurosis of the external oblique muscle (again see Fig. 255). A slender pair of artery forceps is passed through this opening and through the lower muscular fibres of the internal oblique and transversalis muscles, following the left index-finger as it is withdrawn through the inguinal canal, and finally out of the superficial opening (Fig. 256). With the same instrument the isolated sac is grasped and drawn through the canal and through the narrow opening in its anterior wall, that is, in a lateral direction from its upper end.

The hernial sac now hangs through a narrow opening above Poupart's ligament (Fig. 257). It is drawn out as much as possible, and then, as Heliodorus did, and as Ball has recently advised, it is energetically twisted. The sac is, however, not removed nor ligated, but is strongly drawn down and laid over the outer surface of the aponeurosis of the external oblique muscle and against the superficial ring; in other words, running superficially to, and in the direction of, the inguinal canal.

By this tension on the sac, as is shown in Fig. 258, the anterior wall of the unopened inguinal canal, and especially the tense aponeurosis of the external oblique muscle, are pressed inward and backward into a gutter.

As the twisted sac lies tensely stretched in this manner, deep silken sutures should be applied, beginning at its upper and outer extremity. These are passed above the twisted sac, through the fibres of the aponeurosis of the external oblique muscle and the underlying muscle-fibres of the internal oblique and transversalis, through the

* There is no letter *w* in the French alphabet. This is Dr. Macewen's misfortune.

twisted hernial sac itself, and then including the ligament of Poupart beneath it. We must be careful not to sew into the external iliac vessels, and the finger-tip introduced deeply into the canal, and crowding back the spermatic cord, is our guide as to the deep structures embraced.

These sutures—five to seven or more—bring together also the pillars of the superficial ring, to which the lower end of the hernial sac is fastened. In case of a long sac, all that extends below the superficial ring is cut away.

The operation is more certain when the upper suture can be deeply applied laterally from the place of entrance of the spermatic cord into the abdominal wall.

In tying the sutures, begin with the highest first. The finger-tip, once more introduced within the canal, is our guide as to when the deep parts are brought properly together thereby. Finally the skin-wound is sutured.

No drainage is used as a rule, and, save in exceptional cases, no truss is advised afterwards. The patient—in those cases healing *per primam*—averaged only seven and a half days in bed. This was not Kocher's wish, however, but due to the limited hospital space. He says, "we agree with Macewen that it is right and desirable that after a radical operation the patient remain six weeks in bed, and not return to work until after eight weeks."

Method of Dr. Joseph D. Bryant.[1]—This consists in isolation of the sac—after exposing by incision the whole length of the canal and the deep ring—and then weaving the empty sac in and out, across and across the long axis of the canal, through four slits cut in the external oblique aponeurosis. Thereby the sac is made at once to oppose a return of the hernia, and also to aid in bringing more closely together the hernial parts.

The exact mode of weaving the sac is clearly shown in the accompanying illustrations, Figs. 255, 256, and 257.

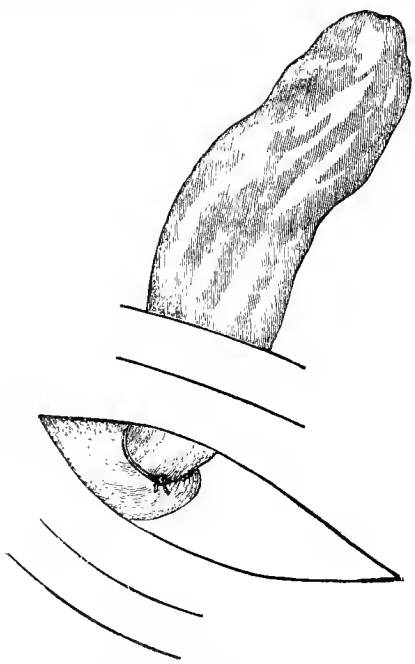

Fig. 255.—Sac going through Upper Slit of Inner Pillar.

A case of sloughing of the sac following its ligation has led Dr. Bryant to cease tying it in this technique. To this extent, therefore, Fig. 255 is now incorrect.

Finally the original slit in the external oblique aponeurosis is closed, and the superficial ring narrowed, with quilted catgut sutures, which are also to be carried through the sac beneath for added solidity; over all the skin is to be sutured.

Dr. Bryant remarks: "It is my opinion that this method cannot be applied indiscriminately, as can the open method, since it frequently happens that the sac is

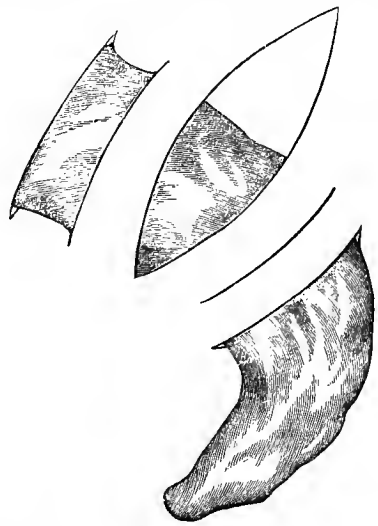

Fig. 256.—Sac going through Slits of Inner and Outer Pillars.

illy developed, or so much damaged by isolation that it will be unwise to hope for particular benefit from the weaving process, even if it be possible to employ it; and,

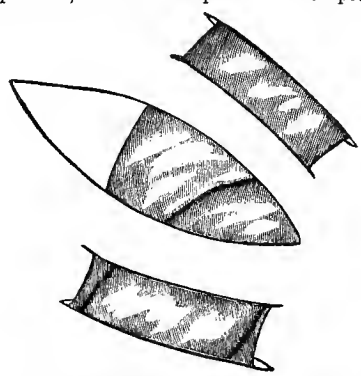

Fig. 257.—Sac passing through Outer Pillar and beneath Inner Pillars.

too, not infrequently, the external pillar of the ring may be found to be so narrow and attenuated as to render its slitting impracticable." Recently Dr. Bryant has not

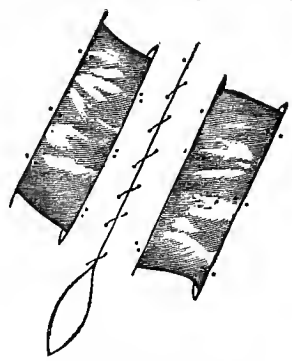

Fig. 258.—Quilted Tissues.

performed this operation so frequently as heretofore, and so informs me.

Method of Dr. George R. Fowler.—This surgeon makes

his incision, and treats the sac in the same manner as does Bassini. He then follows a plan of his own, to be described, which is a modification of the *method of Postempski*. In this latter plan the technique throughout is like Bassini's, save that Postempski permanently removes the spermatic cord from the inguinal canal, thereby being enabled to close the latter more completely. Postempski lifts out the cord as far as the deep ring, displacing it in a direction upward and toward the median line, and attaches it in its new position (just beneath the skin, and superficially to the external oblique aponeurosis) by loose loops of buried catgut suture.

Dr. Fowler's method (used for two years, now) differs from this, the Bassini-Postempski, in two respects, viz., as regards the character of his incision, and in respect to a peculiar method of suturing. He first slits the abdominal wall, "an inch or more," straight upward from the deep ring, and going as deeply as the peritoneum. Into this slit he lifts the cord, and holds it there, at the highest point possible, by "a loose loop of catgut suture placed at a proper distance above the internal ring." The integument and fascia are dissected up from the aponeurosis of the external oblique for a distance toward the median line sufficient to permit the placing of the spermatic cord in this, its new position, so far as its length will allow.

"Both ring and cord, as well as the inguinal canal being now cleared, the next step to be taken consists in a close approximation of the margins of the gap left. In order to accomplish this in the most perfect manner all drainage of the wound must be dispensed with, and it goes without saying, in these days, that the most rigid aseptic precautions have been adopted, in order to make this entirely safe. If antiseptic fluids have been used these should be washed away with sterilized salt-solution, or a solution of the blood-salts in normal proportions. In this way any fluid remaining approaches in character normal connective-tissue fluid, and no irritation is produced by its presence.

"The wound is now ready for suturing. In order to secure proper layer-to-layer approximation of the divided and separated structures it was formerly the custom to secure these by means of buried catgut sutures. I have abandoned this method ever since employing the Bassini-Postempski procedure, and have substituted for it a method devised by myself, and which I have heretofore described as the "crossed suture." The material employed is *crin de Florence*, or silkworm-gut. Firm and evenly rounded strands of this are selected. In using it the strand is threaded at both ends upon large and full-curved Hagedorn needles. In order to avoid troublesome and annoying unthreading of the needles during the manipulation, I secure these to the thread by passing the end of the latter through the eye of the needle a second time from the same direction as that from which it was first passed. By this means a firm loop or "bight" holds the strand securely to the needle, Fig. 259 (*Annals of Surgery*, May, 1892).

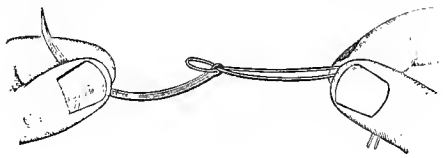

FIG. 259.

"The strand being thus secured to the needles the latter are passed from behind forward, one through each edge of the divided lowermost layer. The latter consists essentially, in the case of an ordinary indirect inguinal hernia, of the muscular structures and conjoined tendon upon the inner margin, and Poupart's ligament upon the outer. At the points where the transversalis fascia presents itself as the floor of the canal, a fold of the latter is included in the loop. Care should be taken in this part of the manipulation not to wound the external iliac vessels. The needles, after emerging (the loop being drawn taut) each from its respective side, are reversed as regards position; that which passed through Poupart's ligament being now carried to the inner side and passed through the skin, again from behind forward, while that which included the inner margin of the lowermost layer, or muscular structures and conjoined tendon, is passed through the skin at the outer margin in the same manner. The thread is therefore crossed on a level with the plane which represents the space between the two layers. Upon drawing upon the ends of the threads the loop which includes the muscular structures and conjoined tendon upon the inner, a fold of transversalis fascia in the floor, and Poupart's ligament upon the outer side, of the wound, is tightened, and perfect approxima-

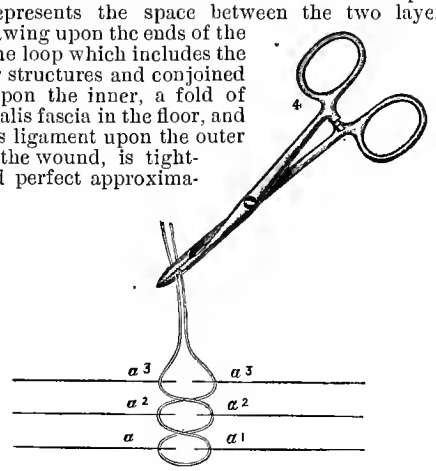

FIG. 260.

tion of these structures results. By tying the suture over the skin the incision is completely closed. Fig. 260 (*Annals of Surgery*, May, 1892) shows the "crossed suture," in this case crossed a second time.

"The sutures are placed about three-eighths of an inch apart and a sufficient number are employed to close completely the wound, no drainage being employed. All the sutures are placed in position before any are tied. In accomplishing the latter it is well to begin from above and as each is drawn taut a finger is carried to the bottom of the wound in order to assure one's self that each is fulfilling its purpose. A strip of protective and the usual dressing complete the procedure.

"The sutures are left in place for at least three weeks; I have left them in for five weeks with no ill effects. They are removed as an ordinary suture by simply cutting the thread upon one side of the knot and making traction upon the other. No difficulty is found in withdrawing the silkworm-gut, the latter readily following the figure-of-eight track which it forms.

"I never permit a patient thus operated upon even to sit up in bed for the first six weeks following the operation. This, at the present time, I consider an important adjunct to the operation, although further experience may shorten this time somewhat in selected cases. In persons in whom, from long truss wearing or other causes, there is a loss of resiliency of the wall of the abdomen, it is well to prolong the stay in bed for a fortnight longer, and to employ, in addition, massage and electricity, following the healing of the wound.

"The advantages claimed for this method of operation relate, *first*, to the plan of placing the cord in such a position as to render it next to impossible for a knuckle of intestine to follow it in its course. Under all circumstances in which a recurrence is favored or produced, the duration of the force is from within forward and downward. When the cord is made to assume a course upward and then inward before making its descent in the direction of the scrotum, nothing short of the patient standing on his head will favor the entrance of a portion of intestine alongside of the cord, and permit it to follow its course. It may be said that the weight of the testicle will tend to straighten the cord finally; this is true to a certain extent, but the manner of placing the sutures here described will prevent this, for the reason that the cord

is held away from the line of incision by being retained entirely outside of these, independently of the chromicized catgut loops which fasten the cord in its new position. *Second*, the crossed suture secures, in the approximatiou of the edges of the divided layers separately, all the advantages of the buried catgut suture ; being removable at will it presents none of the disadvantages arising from the uncertainty as to the length of time which the latter may be depended upon to hold securely. In addition to this, the crossed suture firmly grasps and securely holds the several layers, not only edge to edge, but surface to surface. The result of this is a firm and solid wall, extending from the parietal peritoneum to and including the skin-surface. *Third*, prolonged maintenance of the dorsal decubitus insures stability and firmness of this wall, and at the same time, aided by massage and faradization, it restores the relaxed and thinned abdominal wall to some approximation to the normal condition."

Dr. Fowler has used this method up to date in thirty-three cases ; and has had but one recurrence—a patient with femoral hernia, in whom suppuration and extensive sloughing occurred. The author advises against the use of a truss after the operation.

Method of Dr. George A. Baxter.[8]—This consists in an incision exposing the whole length of the inguinal canal to the deep ring, followed by a second cut going directly upward from this ring through the entire abdominal wall and exposing the bowels for a distance—varying as to number of inches in different cases—"sufficiently far to enable the sac to be engaged in it without being too much folded upon itself."

The sac, after a very thorough dissection to the highest possible point, is tied at a level which would be "within the canal" if the sac were still lying there. Then the sac is turned vertically upward from the deep ring and pressed deeply into the upper wound. Any excess at the free end of the sac is cut away.

Two lines of sutures are next inserted. The deepest pass first through the skin and directly into the peritoneal cavity, then out through the sac in its new position, then into the belly again, and so out of the skin on the opposite side of the wound. About four or five of these stitches are inserted transversely, going from the highest point down to the deep ring. Next, a more superficial row, about as numerous, and covering the same extent of wound ; but these only pass from the skin to the peritoneum, and run *over* the sac, and embrace the musculo-aponeurotic coverings of the abdomen and the skin.

The author points out the danger of ventral relapse from allowing, while suturing, the muscles to retract, as they will to different degrees, and of passing the needles without first remedying this. One should seize the muscle-edges and draw them flush and even with the skin, and, while holding the wall thus, pass the needles.

Next one or two "curved or crucial sutures are passed at the internal opening of the canal from below upward, dipping over the cord (which is placed to the outer side of the incision, and still in the canal) but entering and passing through the tissues after the manner adopted in the majority of operations for ruptured perineum—traversing them, in other words." Now tie all the sutures passed.

Finally, "the hernial canal and scrotal opening are closed with deep suturing." (As to this, no more definite statement is made, nor is the kind of suture-material named.) No drainage is to be used unless we find the sac or its contents diseased.

The author calls attention to the "necessity for careful removal of all fat from the neighborhood of the internal opening, and the freshening of the edges of the tissue at this point for better union."

Dr. Baxter claims among its advantages that this plan "deflects all expulsive efforts from the ring and canal to the abdominal parietes, thereby lessening greatly the liability to a recurrence in the old channel ; and, by doing so, leaves the ring and canal in a perfectly quiescent state during the whole progress of healing."

This operative procedure is so recent as to have no list of cases to show as yet. Dr. Baxter gives illustrations of methods and results in one difficult case.

Method of Dr. A. Wölfler.[9]—This, the most complicated of possible methods for radical cure, has, I think, for this

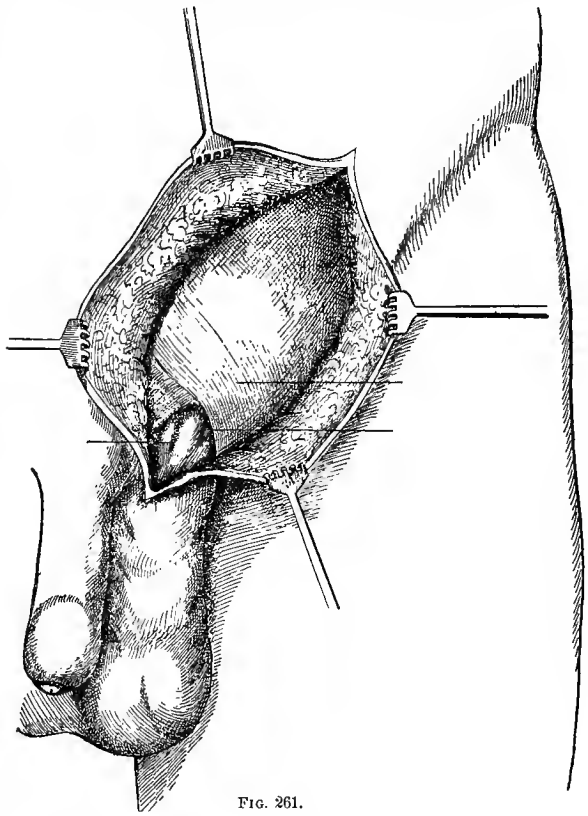

Fig. 261.

reason been but little tried by others than Wölfler himself. It is, however, so ingenious in several respects as certainly to be deserving of accurate description. Most of the steps he has used for four years past. These are :

3. Isolation of the blind (distal) end of the sac (Fig. 263); and opening this freely by aid of several pairs of forceps (Fig. 264).

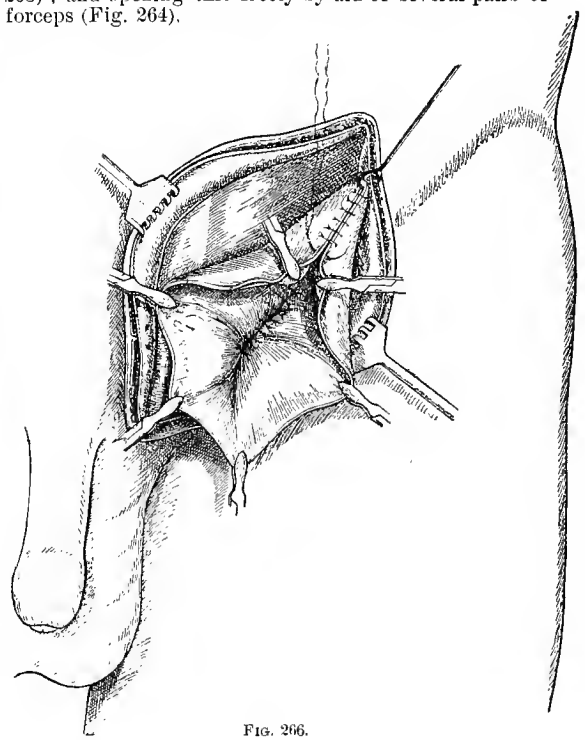

FIG. 266.

4. Closure of the neck of the sac by suturing (silk), by either of two methods (Fig. 264).

5. Then scorching of its interior by actual cautery (Fig. 265).

6. Final closure, by suture, of distal portion of

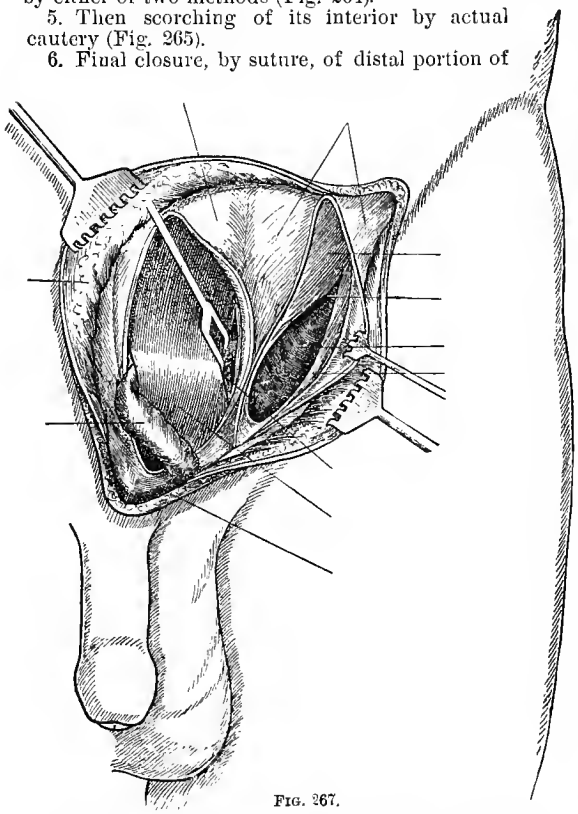

Fig. 267.

sac, Fig. 266, leaving it still in inguinal canal. In case the sac is easily peeled up, it may, instead

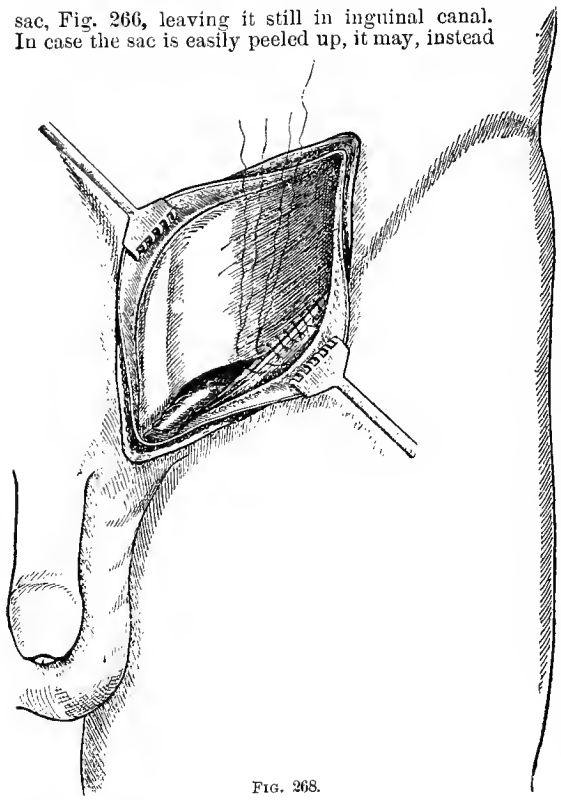

Fig. 268.

of step 5, be cut away near its first-named line of sutures after the cauterization.

7. The cord must now be displaced from the deep ring and brought as far inward as is possible.

8. Temporary castration, by pulling the testicle, attached to its cord, out of the scrotum, then tucking it through an opening behind the sheath of the rectus muscle of its own side, then out through a slit between the two recti, and so back again home (Fig. 267). This device has only as yet been used four times, and but recently. The inguinal canal is now, of course, empty, save for the scorched and doubly sutured sac.

9. Narrowing of the canal and deep ring by sewing snugly over the sac in them first the transversalis mus-

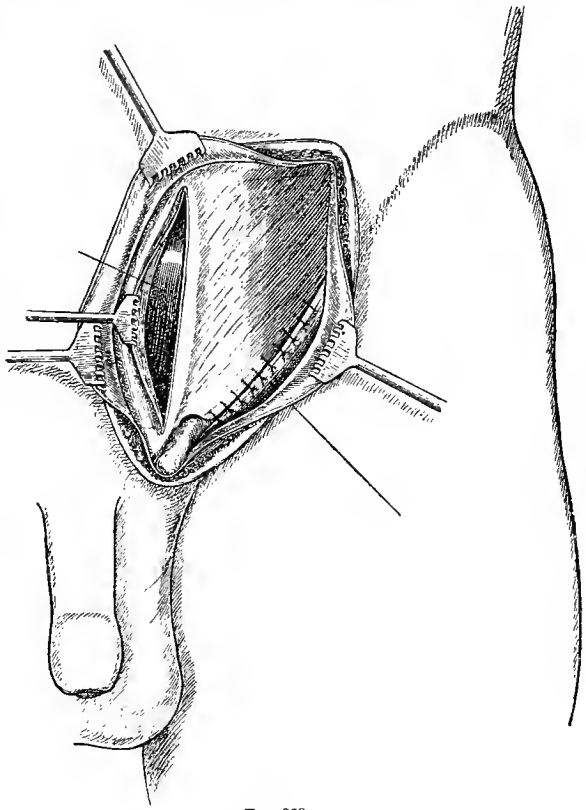

Fig. 269.

cle, and next the internal oblique, each to the deeper, shelving portion of Poupart's ligament (Fig. 268).

10. Opening sheath of rectus muscle (Fig. 269).

11. Displacement outward of this muscle until it is sewn, like the previous muscles, to Poupart's ligament (Fig. 270); or else to the under surface of the aponeurosis of the external oblique, on the outer side of the cleft in the latter. In addition, the cut sheath of the rectus, or its anterior portion at least, is so sutured.

12. Closure of the split external oblique aponeurosis, and obliteration of the superficial ring, by suturing, even down to the pubic bone (Fig. 271).

13. Suture of the integument, over a small drainage-tube.*

In making the superficial incision this should run, not parallel with Poupart's ligament, as the cut (Fig. 261) would indicate, but rather more nearly in a vertical direction. The same is true of the direction in which the external oblique aponeurosis is slit. Consequently there is a much broader aponeurotic surface than merely Pou-

* In Figs. 268, 269, 270, and 271 it is evident that the cord is wrongly drawn, and should have been made to appear running in its new position, from between the two recti muscles, downward and outward to the scrotum.

part's ligament to which to sew the two deeper muscles. Also, the rectus does not have to be dragged so far outward for suture (as shown in Fig. 270) as otherwise would be the case.

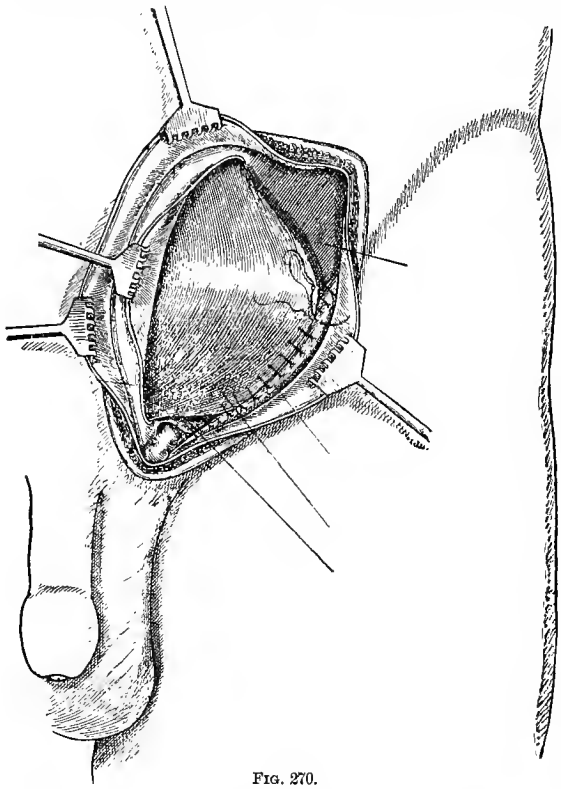

FIG. 270.

As to the further treatment of the cauterized and stitched sac, the author states that he commonly crowds it as much as possible against the deep ring, and then sews the muscles over it as stated. "When (exceptionally) this cannot be done, the sac is drawn, before this suturing, toward the scrotum ; and any excess in length is divided opposite the superficial ring by either cautery or knife."

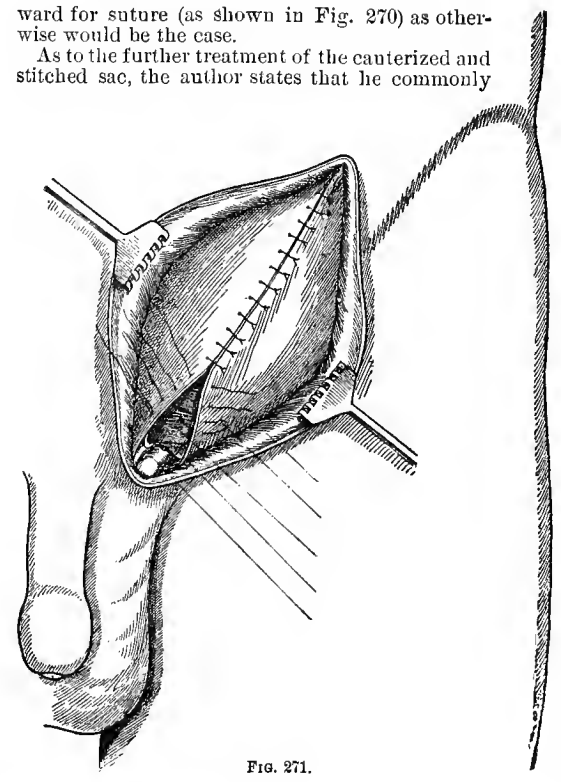

FIG. 271.

Regarding the temporary castration, Wölfler advises inserting a thread through the scrotum at the location of the divided gubernaculum, for the purpose of readily finding it again, so as to replace, by a stitch, the testis in its exact former relation to the gubernaculum.

It will be observed that Wölfler indulges, as a rule, in eight distinct lines of suturing : 1, The neck of the sac ; 2, after cautery, the more distal portion thereof ; 3, the transversalis muscle ; 4, the internal oblique ; 5, the rectus ; 6, its cut sheath, or the anterior part of it ; 7, the external oblique aponeurosis ; 8, the skin.

In his introductory remarks it is pleasing to notice that he disapproves of Macewen's method, among others, because it is so complicated, so lacking in simplicity !

Method of Dr. Frank.[10]—This surgeon has recently reported two cases in which, after removing the sac as usual, he has carried out a new idea, in endeavoring permanently to empty the canal of the spermatic cord, so that the canal may be obliterated by suturing. This is done by dragging the cord inward until it escapes opposite the superficial ring, when it is tucked down into a neatly fitting gutter of sufficient depth, chiselled from the horizontal ramus of the pubes. The superficial ring, like the rest of the hernial region, is now entirely to be closed by sutures.

Turning now from inguinal to femoral hernia, the writer presents, in closing this study, three recent methods devised for attempting radical cure of hernia escaping below Poupart's ligament, through the femoral ring. It is commonly agreed that, by whatever plan attempted, femoral hernia is somewhat less frequently the subject of relapse than is inguinal. Dr. Marcy has stated in his new work upon hernia, *à propos* of this, that Drs. Macewen and McBurney have recently written him saying that they do not know of a single recurrence in their own operated cases. The widely differing plans, nevertheless, preferred by these two gentlemen may be ascertained by reading the description, in Vol. VIII., of their respective inguinal operations.

Dr. George R. Fowler's method in femoral hernia consists (after the isolation, high ligation, and cutting away of the sac) in the application of his "crossed suture," before mentioned in this article (see Fig. 260). Poupart's ligament is forcibly retracted upward, when the internal opening of the crural canal is brought into view. The first loop of each suture will include, according to its location, either Poupart's ligament or the lower border of the aponeurosis of the external oblique muscle, the vagina vasorum, the pectineus muscle and fascia covering it, and, perhaps, Gimbernat's ligament. The usual care must be exercised, while sewing, not to wound the vessels. The needles are now reversed, the suture crossed, and the margins of the iliac and pubic portions of the fascia lata included in the second loop. The needles are again reversed, the suture again crossed, and the superficial fascia and integument grasped in the last or outer loop, this last being completed by tying the suture upon the outer surface of the skin.

Dr. Salzer[11] first removes the sac and then closes the external orifice by a flap formed from the fascia covering the pectineus muscle turned upward and sutured to the middle third of Poupart's ligament. In this manner the *septum crurale* is replaced by a tough, resistant layer of fibrous tissue. The thickness of the pectineal fascia varies, but it is most likely to be strong enough in old persons and in those who have worn a truss for femoral hernia for a long time.

I think it preferable to oppose to the advance of the bowel a thicker, firmer mass than that made by Salzer's layer of pectineal fascia alone, and have preferred, as a slight but not unimportant modification of his method, to dissect up quite a deep and free flap of pectineus muscle and not alone of its fascial covering, suturing this

to the freshened and well-exposed broad under surface of Poupart's ligament, and thereby solidly filling the space between the femoral vein and the free edge of Gimbernat's ligament. Outside this musculo-fascial flap I also unite the freshened iliac and pubic portions of fascia lata, if need be making a long vertical incision through this membrane, an inch or more to one or other side, to permit easy apposition of the edges, without tension on the sutures; and finally I close the skin-wound; all stitches being preferably of freshly boiled silk.

Dr. Kocher describes as follows the method preferred by him: "In femoral hernia, also, it is necessary completely to isolate the hernial sac serosa, to draw it strongly down, and to tie it as high as possible. With the short and broad pedicle this ligation is not always so easy as it is in the inguinal hernia. Then cut away the excess. Still more difficult is the suturing of the canal. Nothing is to be gained by sewing the remains of the processus falciformis which forms the anterior crural ring, to Poupart's ligament; but here also the deep parts of the femoral canal must be brought together. This is best attained (as we can say after watching the courses which our cases have followed), by passing the sutures through the transverse portion of the pectineal fascia (which, under the name of "ligament of Cooper," covers the pectineus muscle at its insertion into the pubes, and which can plainly be seen on the lower side of the neck of the hernial sac), and drawing it up and firmly suturing it to Poupart's ligament. This causes broadening of the ligament of Gimbernat which covers the inner angle of the femoral ring, and usually gives a sufficiently good closure of the hernial opening."

Dr. Kocher has sometimes also employed the following method in the treatment of the sac: This, having been completely isolated and twisted as strongly as possible, is drawn through a small opening made above Poupart's ligament, and in the manner above described is included in the sutures which are passed through the pectineal fascia and Poupart's ligament for the purpose of closing the femoral ring. *Robert H. M. Dawbarn.*

HISTOLOGICAL FORMULÆ, ETC., RECENT.

That histology is a progressive science is evidenced by the many new and modificatory formulæ constantly appearing; that it is becoming more and more an exact science is shown by the quality and accuracy of the results. Methods are the *sine qua non* and their importance cannot be too greatly emphasized.

Fixation of Tissues.—Fixing, as ordinarily understood, implies the killing as well as a slight degree of hardening of the tissue. Its more precise aim is to cause as nearly as possible, by means of certain reagents, the same relative position, size, and structure of the elements after death as before. This may be more or less successfully accomplished either by the use of an agent that acts instantaneously or one that acts gradually. Rapid fixation perhaps gives the most satisfactory results. It is of course essential that the structures should be alive at the time of fixation, so that pathological or post-mortem changes may be avoided. Plenty of the "fixer" should be used. Fifty to one hundred times the volume of the specimen is a good proportion. It should be changed whenever it becomes turbid. After once being used it is to be thrown away. No universal fixer has as yet been found. With so many varying conditions and peculiarities of structure, experiment alone can decide just which formula is best for any particular case.

According to Kultschitzky[1] the following important rules must be borne in mind in the fixation of tissues: Use those reagents which do not form tissue-like precipitates with protoplasm. This requirement is met by *chromic salts, sulphate of copper, sublimate* and some other salts. Preparations from chromic salts when transferred to alcohol *should be kept in absolute darkness* (Virchow) until the fixing agent is removed so far as possible. Chromic acid transforms protoplasm into tissue-like forms and should be avoided unless its application can be controlled. Fixing fluids should contain an organic acid (*e.g.*, acetic) which changes nuclein into an insoluble state. The acid should be used in a diluted form, as nuclein is said to be soluble in strong acids, or even in weak acids if their action is too long continued. A small quantity of alcohol is also desirable. Strong alcohol dehydrates too rapidly and induces changes in the protoplasm. With the foregoing as a basis, he recommends the following solution: Mix excess of finely powdered bichromate of potash and sulphate of copper in fifty per cent. alcohol and allow the solution to stand in complete darkness for twenty-four hours. A greenish-yellow fluid is the result and this before using should be acidulated with acetic acid (five or six drops to one hundred cubic centimetres). The object to be fixed is placed in this fluid from twelve to twenty-four hours, according to its size and the degree of hardness required, the whole transaction being carried on in the dark to avoid the precipitation of the salts. The specimen is then placed in strong alcohol from twelve to twenty-four hours, after which it may be sectioned in any of the usual ways. The usual reagents for preservation after fixation, alcohol, chromic acid and its salts, are rejected on account of the tissue-changes induced by them; ether, xylol, toluol, or any substance which does not act upon albuminous matter, is recommended.

Osmic acid in the form of vapor or in solution, corrosive sublimate, Flemming's, Kleinenberg's, Perenyi's, Merkel's, and other mixtures have stood the test of time and are too well known to need more than the briefest mention. Tissues fixed in osmic and chromic acids do not readily take the carmine stains. Osmic acid is easily reduced in the presence of organic matter. This is a more important factor than light.

To retard this reduction Lee[2] recommends that the osmium should be kept in the form of a two per cent. solution of osmic acid in a one per cent. aqueous chromic acid solution. This solution serves for fixation with osmium vapors and for the making up of Flemming's solution. All dust should be carefully excluded.

Rabl's Fluid:[3]

One-third per cent. chromic acid	200 c.c.
Concentrated formic acid	4 or 5 drops.

The mixture must be prepared fresh whenever needed. After twelve to twenty-four hours' fixation the tissue is washed with water and the hardening completed in alcohol. It is one of the very best reagents for karyokinesis.

Permanganate of Potash.[3]—This reagent, in a saturated solution, is said to kill even more rapidly than two per cent. osmic acid. It preserves the forms of cells very well and has been found useful in the study of isolated and contractile cells, *e.g.*, spermatozoa.

Carnoy's Fixing Fluid or Acetic Alcohol.[4]—First formula:

Glacial acetic acid	1 part.
Absolute alcohol	3 parts.

The second is:

Glacial acetic acid	1 part.
Absolute alcohol	6 parts.
Chloroform	3 parts.

The chloroform is said to render the action of the fluid more rapid. Acetic alcohol is one of the most rapid and penetrating "fixers" known. It preserves nuclei well, but must not act too long, and admits of most any way of staining. It is applicable to tissues in general and should be washed out with alcohol.

Davidoff's Solution:[5]

Saturated solution of corrosive sublimate,	3 parts.
Glacial acetic acid	1 part.

This has been found very useful for ova, which may

remain in it from half an hour to an hour, then washed for a few minutes in water and carried up through the successive alcohols. This mixture also works very satisfactorily with other tissues and for the rapid killing of many animals.

Another solution, almost as good, consists of:

Saturated solution of picric acid	3 parts
Glacial acetic acid	1 part

The structures are to remain in it for three or four hours and then brought into seventy per cent. alcohol.

Kolossow's Solution.[14]—A 0.5 per cent. solution of osmium in two or three per cent. of nitrate or acetate of uranium is recommended as having very great penetrating power.

Gage's Picric Alcohol:

Distilled water	500 c.c.
Ninety-five per cent. alcohol	500 c.c.
Dry picric acid	2 gms.

It amounts to a one-fifth per cent. solution of picric acid in fifty per cent. alcohol. The tissues are fixed in this solution from one to three days, then washed in sixty-seven per cent. alcohol for two to three days and kept for at least one day in eighty-two per cent. alcohol. They may remain in the latter indefinitely. If small pieces of tissue are used the time for each step may be abridged; if large, the time should be lengthened. This "fixer" is of quite general application and admits of any of the usual methods of staining.

Picric acid should *always be washed out with alcohol* (Lee).

This reagent is said to transform albuminates into an insoluble state. After the removal of the acid the tissue can be colored with any stain. It is recommended for chitinous structures on account of its penetrability. It has also some decalcifying power.

Zinc Chloride.—Broca,[6] in 1879, recommended a ten per cent. alcoholic solution of this salt for the preservation of gross preparations of the brain. Grandmaison (*Comptes rend. hebdom Soc. de Biol.*, I., 1889) has considered "De l'emploi des solutions de chlorure de zinc pour la fixation des éléments anatomiques." This reagent has given excellent results on brain-tissue for histological purposes in the following solution:

Ninety-five per cent. alcohol	100 c.c.
Zinc chloride	5 gms.

Its action is rapid and even. After two to three days' immersion the tissue is placed in ninety-five per cent. alcohol until thoroughly hardened and dehydrated, when it may be imbedded and cut in any of the usual ways. It stains very readily in hematoxylin or carmine.

Lemon-juice,[7] fresh and filtered, has been warmly recommended by Van Gehuchten as a fixative for nuclei. Fix for five minutes, wash well with water, and stain with methyl green.

Alcohol.—Two grades are sometimes employed. Dilute alcohol is often useful, in that it is strong enough to exert some coagulating power, but has sufficient water to render its dehydrating action feeble and innocuous. Absolute alcohol kills quickly and the tissues are not allowed to become deformed. Alcohol, however, is chiefly useful as a "fixer" in connection with some salt dissolved in it, as corrosive sublimate, picric acid, etc.

Pyridin.[8]—A coal-tar product, possessing the peculiar property of being miscible with either oils or water, and coagulating albuminates with a neutral reaction. Hardening is effected in an incubator in about eight days; with small specimens less time is required. The tissues are at once hardened, dehydrated, and cleared, and can be easily sectioned and stained. The anilin dyes dissolve very readily in pyridin. The sections may be mounted in balsam, or after four days' hardening transferred to water, in which case they take up hematoxylin and picrocarmine very well. The reagent gives the best results with nervous tissue. It has also been found useful in the study of bacteria. The odor is very penetrating and rather disagreeable.

Heat.—Heat is very efficacious in killing suddenly and coagulating albuminous substances. "It has the great advantage of allowing of good staining subsequently and of hindering less than any other method the application of chemical tests to the tissues."[9] Heat is not applicable to all organs or organisms, nor is it always easy to determine the exact degree of temperature suitable for each structure; 80° to 90° C. will generally be amply sufficient, and very frequently it will suffice not to go beyond 60° C. A few seconds' exposure is generally enough. When the protoplasm is supposed to be coagulated throughout the structures are brought into thirty to seventy per cent. alcohol, if water is employed as the heating agent. The efficacy of the ordinary fixing mixtures is largely increased by heating them.

Small objects (Protozoa, etc.) may be brought into a little water in a watch-glass or on a slide, and heated over the flame of an alcohol lamp. For larger objects the water or other liquid may be heated beforehand and the animals thrown into it. For the fixing of eggs (amphibian and others) heat has given most excellent results.

Decalcification.—Bones or calcified tissue contain a considerable amount of inorganic substance, represented chiefly by the phosphate and carbonate of lime. These salts are soluble in various acids, and when once removed the organic constituents are left behind, leaving the bone flexible, elastic, and more or less translucent, and, with proper imbedding, admitting of easy sectioning. To obtain the most satisfactory results the bone must be thoroughly fixed and hardened like any other tissue, before being put into the decalcifier. Reagents which are said to harden and decalcify at the same time are of doubtful utility for fresh specimens.

A general but important rule to bear in mind is to employ the acid in a very weak solution, in order to make as little change as possible in the soft tissue it leaves behind. When the lime is chiefly in the form of a carbonate, as in the skeleton of *Echinoderms*, the acid must be added very gradually. The specimen should be immersed in water in a glass vessel, and the acid added drop by drop until the appearance of air-bubbles shows that it is taking effect, the remainder of the acid being added as required. When the lime is mostly in the form of a phosphate, as in the bones and teeth, the acid may be used in a stronger solution.

The most widely used reagent for this purpose is nitric acid. It exerts a great gelatinizing power even in weak solutions, thus tending to deteriorate the soft structure if acting alone or in aqueous solution. It has been found that the gelatinizing or softening action might be greatly hindered by the use of an alum solution (Gage). Care must be taken not to allow the objects to remain too long in the decalcifying fluid, or decomposition will ensue.

Gage's Methods.[18]—The fresh bone, tooth, or calcified cartilage, is fixed and hardened by any of the approved methods, as for soft tissues. Picric alcohol has been found very satisfactory. The tissue is then ready for the following decalcifying mixture:

Sixty-seven per cent. alcohol (95 per cent. alcohol, 2 parts; water, 1 part)	100 c.c.
Strong nitric acid	3 c.c.

Other things being equal, the smaller the volume of the bone the more rapidly will it decalcify. The fluid should be changed after twenty-four to forty-eight hours. If the specimen is large it may be necessary to change the fluid two or three times. A stay of from ten to fifteen days does not seem to injure the soft structures. If there is no gritty feeling upon the introduction of a needle, the decalcification is complete. Upon removal from the decalcifier, the tissue is rinsed a minute or so in water, then placed in sixty-seven per cent alcohol one to two days, then in eighty-two per cent. until ready to section.

Small animals, *e.g.*, salamanders, treated by this method give most excellent results for skull, brain, etc.

Second Method.—After fixing, the tissue is put into the following mixture: A saturated aqueous solution of alum is diluted with an equal volume of water, and to each 100 c.c. of this half-saturated alum solution add

5 c.c. of strong nitric acid. The mixture is changed every two or three days until the decalcification is complete. It is somewhat more rapid than the first decalcifier. After decalcification the tissue is thoroughly washed in water and carried through the alcohols as before.

For teeth this is perhaps the better decalcifier. Both mixtures preserve the soft structures, marrow-cells, ciliated epithelium, etc.

In the first the alcohol, and in the second the alum, serves as a restrainer, preventing the gelatinizing and destructive action of the nitric acid.

Thoma's Method.—Bones or other calcified tissue, either fresh or hardened, are placed in alcohol 95° Tralles until completely saturated, and then transferred to a solution consisting of:

Alcohol (95° Tralles)	5 parts.
C. P. nitric acid	1 part.

in which they are left several days, being frequently shaken. The fluid should be renewed and shaken until the tissue is completely decalcified. The fluid acts quickly, the calcic nitrate formed being quite soluble in weak alcohol. This may be proven by adding to the above solution a surplus of precipitated carbonate of lime; upon evaporating 100 c.c. of the filtrate there will be found 8.67 grms. of calcic nitrate. Large pieces of tissue may be decalcified in two to three weeks. They are then washed in alcohol and put into a vessel containing a surplus of precipitated carbonate of lime in alcohol 95° Tralles. This mixture is also shaken up and renewed, until every trace of the acid is removed from the tissue, which takes usually from eight to fourteen days. The specimens should be left in the solution even a short time after litmus-paper shows no acid reaction. Most of the deposit of the carbonate of lime can be removed from the specimen with a spray of alcohol; the small particles left do not interfere. The deposit may be avoided by wrapping the specimen in filter-paper, but it takes longer to remove the acid. Or a dialyzer with a diaphragm of filter-paper may be used. Large pieces of dense tissue are rapidly decalcified and the acid completely removed, no swelling of any account occurs, and the soft structures undergo little or no change.

Hydrochloric Acid.—This acid also has an extensive use, but it has the disadvantage of causing considerable swelling. To obviate this to a greater or less extent it may be used in combination with chromic acid or alcohol. Or a three per cent. solution may have added to it ten to fifteen per cent. of common salt. Or (Waldeyer) to one thousand parts of a one-tenth per cent. solution of palladium chloride may be added ten parts of hydrochloric acid.

Lactic Acid.[9]—This is said to work well in ten per cent. or stronger solution, being more rapid than picric acid, and as applicable for embryonic and small bones as for older calcified tissue.

Phosphoric Acid.[9]—This has also been recommended in ten to fifteen per cent. solutions. The tissue must be immersed for a long time. Unless absolutely pure acid is used the tissue does not stain well. Considerable precaution must also be taken in the handling of it.

Chromic Acid.—This reagent is used for decalcifying, generally beginning with a weak (one-tenth per cent. solution) and passing to the strong (one per cent.). Bone should remain in it from two to three weeks.

Haug's Phloroglucin Method.[9]—One of the most rapid of the decalcifying agents. It preserves the structures perfectly, except blood, which it modifies considerably. The method was introduced by Andeer, who used the phloroglucin in combination with hydrochloric acid, but with variable results. The substitution of nitric acid removed this difficulty. The solution is prepared by warming 1 gm. of phloroglucin in 10 c.c. of C. P. nitric acid. This must be done slowly and carefully. Soon a dark ruby-colored solution is obtained; to this is added 50 c.c. of distilled water. If a larger quantity of the fluid is desired, 10 c.c. of the acid are added to every 50 c.c. of water, until the volume has reached 300 c.c., which is the limit of the protective influence of the phloroglucin.

In this solution the pieces of well-fixed and well-washed material are placed. Fœtal or young bones, as well as those of the lower vertebrates, are decalcified in half an hour. Older and harder bones require but a few hours.

A twenty per cent. solution generally suffices, although thirty-five per cent. may be found useful for teeth. If rapidity is not so essential, the following may be used:

Phloroglucin	1 part.
Nitric acid	5 parts.
Alcohol, ninety-five per cent.	70 parts.
Distilled water	30 parts.

After decalcification the bones are washed in running water for about two days. The sections stain well and do not fade.

Desilicification.—Objects should be first hardened in alcohol, then placed in alcohol in a vessel made of lead, gutta percha, or glass coated with paraffine. Hydrofluoric acid is then added drop by drop, care being taken to avoid its poisonous fumes. Contact of the acid with the skin causes wounds difficult to heal. Small sponges and other similar siliceous objects, by remaining a few hours or a day in the above solution, are wholly deprived of their silica, while the tissues do not suffer.

Staining.—The chief function of a stain is to differentiate certain tissue-elements, or, as in a successful gold chloride impregnation of nerve-endings, a whole tissue or group of tissue-elements. The former Lee[2] designates as cytological selection, the latter as histological selection. The precise action or combination of stains is as yet very obscure. Living tissue has no affinity for ordinary stains. Certain special reagents which do color living tissues, temporarily at least, will be noted later. A living cell is never at rest, and only after it has become considerably weakened will it permit the stain to act. The coloring of the nucleus is a sign of death. If the cell recovers, the cytoplasm will ultimately throw off the stain.

Furthermore, according to M. Flesch,[10] a favorable stain, *e.g.*, cyanin, produces a much different result in a "fixed" preparation than in a living one. The parts affected in the dead preparation can never be similarly affected when alive.

Some stains are successful only after previous treatment of the tissue with easily reducible combinations. By control experiments it is seen that the staining extends only as far as the metallic precipitate. The original constituents of the tissue are not stained, but the chemical products, probably the metal albuminates resulting from the treatment with hardening agents. There is reason for believing that the parts which, when living, are more highly endowed physiologically, take on a deeper color. The methods of fixing and hardening count very much, therefore, toward the successful action of a stain, and must be taken into careful consideration when making a selection. Tissues fixed in chromic acid or its compounds do not take the carmines well, while hematoxylin acts very readily on such tissues.

Lee[2] considers two methods of bringing about selective staining, the *direct* and *indirect*. With the former the operation must be watched and stopped at just the right stage, when the desired elements are sufficiently colored, otherwise the stain acts on the other parts and a diffuse color is the result. With the *indirect* (by far the more common) the tissues are over-stained and the superfluous color afterward removed by some reagent (usually acidulated alcohol).

Stains may be used in aqueous or alcoholic solutions. Each is useful in its own way. With the former there is danger of maceration if the tissue is delicate and left too long in the fluid. With some tissues the swelling induced by the water may be an advantage, and results not attainable by any other method are produced. Alcoholic stains possess the property of preserving the structures while the coloring is going on. Considerable time is saved by not being compelled to carry the specimen through as many grades of alcohol, and the danger of tearing delicate parts by osmosis is likewise prevented.

Structures may be stained after having been imbedded

and cut, *i.e.*, in the form of sections, either before or after fastening to the slide, or they may be stained in bulk before being imbedded. Here again there are certain advantages peculiar to each method. A more even distribution of color is perhaps insured with aqueous or weak alcoholic stains.

According to Whitman,[11] the more important qualifications of a dye for staining *in toto* are the following: (1) It should *penetrate* readily, so that its action on the deeper and more superficial parts may be as equable as possible. (2) Its action at full strength should be *intense*, capable of imparting any desired depth of color. (3) It should give a *differential* rather than a *diffuse* staining; *i.e.*, it should act with unequal degrees of intensity on the different elements of the cell, thus contributing to sharpness of definition. (4) Its *preservative* qualities should be sufficiently pronounced to enable it to act any required length of time without causing maceration. (5) The color imparted should be *permanent*. The differential character of the stain may be strengthened by washing a few minutes in slightly acidulated alcohol. A rather broad generalization, then, would be that aqueous solutions are more adaptable for sections or for very small and easily penetrable organisms, while for staining in bulk alcoholic solutions are to be preferred. Too strong an alcoholic solution of stain will cause diffuseness of color. The percentage employed may be as high as seventy per cent.

Any system of classification of stains must be extremely artificial and inadequate. Stains themselves may be derived from *organic* or *inorganic* sources. As to their use, they might be grouped according to their action on *fresh* or *hardened* tissue. A more common and perhaps better division would be their affinity, either chemical or cohesive, for only certain parts of the tissue, *i.e.*, *selectivity*; or for the general and indiscriminate coloration of the whole tissue: *diffuseness*.

The following table may serve as a convenient index:

Diffuse or general stains.	Eosin, picric acid, and other aniline colors.				
Differential or selective stains.	Nuclear.		Metallic.	Intra vitam.	
	Fresh tissues, color temporary.	Hardened tissues, color more or less permanent.	Silver nitrate, palladium chloride.	Methyl blue, cyanin.	
	Methyl green, aceto-carmine.	Hematoxylin, carmines.			
	Some aniline colors.				

Hematoxylin.—This, except for permanency, is perhaps the best all-around stain for animal and vegetable tissues. It stains alcoholic, osmic, and chromic acid preparations very readily, but with the latter care should be taken that all of the acid is extracted, or fading will soon ensue. Hematoxylin is the active principle in the extract of logwood. As it is not very readily or easily extracted, it had better be obtained from the market already prepared. None of the solutions of hematoxylin are perfectly stable, only one or two are fairly so (Lee).

Over-staining may be corrected by the use of weak acids. The tissue should be re-neutralized with ammonia to prevent fading. This is quite likely to occur even with the greatest care.

Hematoxylin solutions are not ready for use immediately after being made up. They must first "ripen," according to the mixture, for a few hours, or days, or months. The ripening process, according to P. Mayer,[12] is due, not necessarily to light, but to the air, which causes the oxidation of the hematoxylin. From the products of oxidation, or from treatment with alkalies, there may be obtained the active coloring principle, hematein, or ammonia-hematein, which in trade is known as hemateinum crystallisatum. It is a brown-red powder and soluble in either distilled water or alcohol. The solution should remain clear upon the addition of acetic acid.

The hematein may be prepared as follows: Dissolve 1 gm. of hematoxylin with the aid of heat in 20 c.c. of distilled water, filter, add 1 c.c. of caustic ammonia (specific gravity 0.875), and put the purple fluid into a dish large enough to allow the liquid to cover the bottom to the depth of ½ c.c. Protect from dust and allow to evaporate. The amount of dry ammonia-hematein is about equivalent to the hematoxylin first used.

Mayer's Hemalum:

(*a*)	Hematein or ammonia-hematein	1 gm.
	Ninety per cent. alcohol	50 c.c.
	Dissolve by the aid of heat.	
(*b*)	Alum	50 gms.
	Distilled water	1 litre.

Mix the two solutions, cool, and filter. A crystal of thymol may be added to prevent moulds. Quite large pieces become intensely stained in twenty-four hours, and the stain apparently gives as good results as Böhmer's solution. For most purposes it is better to dilute with water or a weak alum solution. For a good nuclear stain wash out with a one per cent. alum solution.

An acid hemalum may be obtained by adding to the above solution (*a* and *b*) a two per cent. solution of glacial acetic acid. This is said to give a more precise color than the ordinary hemalum. Remove the acid by simply washing with water.

On account of certain defects found in Kleinenberg's mixture (alcoholic), Mayer recommends the following solution:

Hemacalcium:

Hematein or ammonia-hematein	1 gm.
Aluminium chloride	1 gm.

These should be rubbed together in a mortar very thoroughly.

Glacial acetic acid	10 c.c.
Seventy per cent. alcohol	600 c.c.
Calcium chloride	50 gms.

Mix the alcohol and acetic acid and add the hematein aluminium chloride. When dissolved add the calcium chloride. The fluid is red-violet in color. If the objects are stained too red, treat with two per cent. aluminium chloride dissolved in alcohol, or in a one-half per cent. to one per cent. solution of acetate of sodium or potassium in absolute alcohol.

For some purposes it is well to mix the hemacalcium with one-third of its volume of glycerine (*e.g.*, entoderm or tentacles of hydroids). It is said that the permanency of the fluid is good, but clearing with bergamot or clove oil causes an early fading. Certain oxidation or reduction changes are likely to occur in time and injure the preparations.

Delafield's Hematoxylin.—A well-known and exceedingly useful stain. It will keep for years. See Vol. III., p. 676.

Ehrlich's Acid Hematoxylin:

Water	100 c.c.
Absolute alcohol	100 c.c.
Glycerin	100 c.c.
Glacial acetic acid	10 c.c.
Hematoxylin	2 gms.
Alum in excess.	

This mixture should ripen until it assumes a dark-red color. It will keep for years in a well-stoppered bottle. Sections stain in a few minutes. The stain is suitable for coloring *in toto*, as over-staining does not occur. To get a blue stain, wash out with common drinking-water which is slightly alkaline. It is said that the addition of acetic acid prevents the alum from splitting up into free sulphuric acid, and a basic, lake-forming compound of alumina, as generally occurs in the ordinary (alum) hematoxylin solutions.

Haug's Hematoxylin:[b]

Dissolve hematoxylin	1 gm.
In absolute alcohol	10 c.c.
This is added to an aqueous solution of alum acetate (Liquor aluminis acetici)	200 c.c.

A good nuclear stain and useful in most methods for the nerves. It is quite durable but, like the other hematoxylins, it must be well ripened before use. It is more useful for section than bulk staining. The fluid has at

first a deep violet-black appearance, but after some weeks' ripening it assumes a brown-black color, much like Ehrlich's acid hematoxylin. After treatment for over-staining with acid alcohol, the sections are washed out in water till they become blue.

Gage's Hematoxylin :[78]

Distilled water	200.0 c.c.
Potash or ammonia alum	7.5 gms.
Chloral hydrate	4.0 "
Hematoxylin crystals	0.1 gm.

Place the water and alum in an agate or porcelain vessel and boil for five minutes or more. This is to destroy any germs in the water or alum. Let the solution cool and add sufficient freshly-boiled distilled water to replace what has evaporated from the original 200 c.c. Add the chloral hydrate and dissolve the hematoxylin crystals in 10 c.c. of ninety-five per cent. alcohol, and add to the mixture. Let it "ripen" for a week. If the stain is too concentrated, it may be diluted with freshly-distilled water, or with the mixture of water, alum, and chloral. If the stain is not sufficiently concentrated, add more hematoxylin. With the above sections are usually sufficiently stained in from one to five minutes. It has not been tested for bulk staining. "The boiling is to destroy any living ferments present in the water or alum, and the chloral hydrate is to prevent the development of germs which accidentally reach the solution after it is made."

Benda's Hematoxylin[13] for karyokinetic figures. — Treat the sections with a concentrated solution of cupric acetate for twenty-four hours, in a brood oven. Wash out thoroughly. Stain in a one per cent. aqueous solution of hematoxylin till the sections are black. Extract the superfluous color in hydrochloric acid, 1 to 500, until the sections are yellow. Neutralize the acid in a saturated solution of cupric acetate. Wash. Dehydrate and mount.

Cuccati's Alcoholic Hematoxylin :[14]

Iodide of potassium (C.P.)	25 gms.
Distilled water	25 c.c.
Dissolve and pour into absolute alcohol.	75 c.c.

Keep in a tightly-stoppered bottle and shake repeatedly.

Rub together in a mortar,

Crystallized hematoxylin	75 ctgms.
Alum (C.P.) (Neutral Potash)	6 gms.

Add of the above iodine solution 3 c.c., keeping the mixture well stirred, and gradually add the rest of the iodine solution. Keep in a well-stoppered bottle and leave from ten to fifteen days. Then shake well and after an hour or two filter, and preserve the filtrate very carefully to prevent evaporation and deposit of alum or iodide crystals. This fluid is said to stain only the chromatic part of the nuclei, the color being most deeply fixed in the karyokinetic figures. As over-staining does not occur, the sections may be left in the mixture almost indefinitely, and it is therefore also suitable for bulk staining. It is stated that with proper care the solution never goes bad.

Another Alcoholic Hematoxylin[15]—Make the three following saturated solutions: First, calcic chloride in seventy per cent. alcohol; second, powdered alum in the same percentage of alcohol; and third, hematoxylin in absolute alcohol. Mix one part of the calcic chloride solution with eight parts of the alum solution, and add the hematoxylin drop by drop until a deep purple color is obtained. The color becomes richer by time. If tissues have been hardened in any chromic or acid medium, they should be put into a five per cent. solution of sodium bicarbonate before staining; all trace of acid must be removed.

Iodized Hematoxylin[16] (Sanfelice):

(1) Hematoxylin	0.7 gm.
Absolute alcohol	20.0 gms.
(2) Alum	0.20 gm.
Distilled water	60.00 gms.

After dissolving, solution (1) is poured drop by drop into solution (2). The fluid is then exposed to the light from three to four days. Ten to fifteen drops of the tincture of iodine are added and the fluid, well shaken up, is allowed to stand for some days. Tissues stain in this mixture in from twelve to twenty-four hours. They are then transferred to ninety per cent. alcohol acidulated with acetic acid, in which they remain for the same length of time. Sanfelice believes that this gives the same stain as Böhmer's hematoxylin with tissues previously treated with tincture of iodine; it thoroughly penetrates pieces to be stained *in toto*. Owing to its antiseptic qualities, it keeps longer than most hematoxylins.

COCHINEAL. — Cochineal for some purposes is unrivalled. In aqueous solution it gives a greater richness of differentiation perhaps than alum carmine. In an alcoholic solution it gives a *direct* nuclear stain (Lee).

Partsch's Alum Cochineal.[17]—An old formula; its great utility for histological purposes is a sufficient justification for calling attention to it. Powdered cochineal is boiled for some time in a five per cent. solution of alum, the decoction is filtered, and a little salicylic acid added to prevent mould. Paul Mayer thinks that in some ways it is better than the well-known but later formula of Czokor.

Mayer's New Cochineal Formula :[18]

Cochineal	5.0 gms.
Calcium chloride	5.0 gms.
Aluminium chloride	0.5 gm.
Nitric acid (sp. gr. 1.20)	8.0 drops.
Fifty per cent. alcohol	100.0 c.c.

Pulverize the cochineal, and mix with the calcium and aluminium chlorides in a mortar. Add the acid and alcohol, and heat to boiling. Let the mixture stand a number of days, shaking frequently, and finally filter. The objects must be treated with fifty per cent. alcohol before and after entering the stain.

CARMINE.—Carmine is a most excellent nuclear stain, and pre-eminently adapted for staining *in toto*. The stain should have a slight alkaline reaction; the presence of too much alkali is injurious, rendering the solution unstable; the want of it, on the other hand, deprives the stain of very much of its differentiating effect. Fix the stain by treating with acetic or formic acid before dehydrating and mounting the sections. In botanical preparations, carmine stains most vegetable albuminoids, while starch and cellulose take it up slightly, or not at all.

To obtain the best results with carmine, especially ammonia carmine, on preparations hardened in bichromate, the tissue must be stained before going into alcohol.[2]

Carmine is not readily soluble, even in water, without the aid of some other agent, *e.g.*, ammonia or borax. Carminic acid, the basis of the coloring matter of cochineal and carmine, is readily soluble in either water or alcohol.*

Paul Mayer[18] found, after some experiments, that if carminic acid, or, better yet, ammonia carminate, be treated with acetate of alum, all the acid is precipitated as alum carminate. This substance has the peculiar property of being soluble in either acids or solutions of acid salts (*e.g.*, alum) or in alkalies, or in solutions of alkaline salts (*e.g.*, borax). Water or very weak alcohol must be used for the solvent. An alum solution stains nuclei in the same way as does alum carmine. The borax solution, though weaker, but with other things being equal, gives a redder color. The differentiation is very clear even when washed with water only.

Mayer's Carmalum.

Carminic acid	1 gm.
Alum	10 gms.
Distilled water	200 c.c.

Heat the mixture and filter. The filtrate will remain clear if an antiseptic is added. The solution is of a light red color, shading toward violet. It is said to have good penetrating powers even in osmium preparations, and it is claimed that it is better than alum carmine for staining *in toto*.

Simply washing out with water is likely to leave the

* For the various methods of preparing carminic acid, see the paper by George Dimmock, published in the American Naturalist, vol. xviii., p. 324, 1884.

plasma slightly colored; if this is not desirable use a weak alum solution, or in more stubborn cases weak alcohol. If a less amount of alum is used in the solution, a deposit will form after a time.

As an equivalent for Grenacher's alum carmine, Mayer suggests a one-tenth per cent. solution of carminic acid in a three to five per cent. solution of alum; this may readily be made in the following proportions:

Water	1,000 c.c.
Alum	30 to 50 gms.
Carminic acid	1 gm.

Dissolve without heat. This is a weaker and cheaper solution than Grenacher's, and gives a redder tone to the tissue. The absence of heat is an advantage. Like the alum carmine it requires an antiseptic—a crystal of thymol.

Mayer's Paracarmine:

Carminic acid	1 gm.
Aluminium chloride	½ gm.
Calcium chloride	4 gms.
Seventy per cent. alcohol	100 c.c.

May be dissolved cold or warm. Let it precipitate, and filter. The solution is of a clear red color. Washing out with acid is said to be unnecessary either for sections or masses. If found desirable to wash out for surface views, use a weak solution of aluminium chloride in alcohol, or alcohol with about five per cent. acetic acid. The objects do not become so fiery red after treatment with acid alcohol as with borax carmine. The time limit of staining depends upon the objects. This is claimed to be preferable to borax carmine, because it is in a stronger alcoholic solution, therefore a better preservative and not alkaline.

The carmine formulæ of Mayer have not yet been sufficiently tested to warrant a statement as to whether they are superior, or perhaps inferior, to some of the older formulæ for carmine stains, or if, indeed, they are as valuable to the carmines in general as his hematein method is to the hematoxylins.

An Alcoholic Acid Carmine:

Carmine	4 gms.
Hydrochloric acid	2 c.c.
Seventy per cent. alcohol	100 c.c.

Boil over a water-bath until dissolved, cool and filter. A good stain for general purposes. It is rapid in its action and differentiates well, and should be washed out with seventy per cent. alcohol.

Strasburger's Borax Carmine: [15]

Borax	4 gms.
Distilled water	56 c.c.
Dissolve and add carmine	1 gm.

One volume of this solution is diluted with two volumes of absolute alcohol, and filtered. The nuclei stain with great clearness.

Haug's Alum-Borax-Carmine: [9]

Carmine	1 gm.
Borax	1 gm.
Ammonia-alum	2 gms.

Pulverize and add

Liquor aluminis acetatis	100 c.c.

Boil the solution for half an hour or more. Decant and filter after twenty-four hours. It is good for use in a few weeks. Said to stain sharper and clearer than alum carmine and to be more permanent, also useful for bulk-staining. Wash out in water.

Haug's Ammonia-Lithium-Carmine:

Carmine	1 gm.
Ammonium chloride	2 gms.
Pulverize and boil in water	100 c.c.

After cooling add drop by drop,

Liquor ammonii caustici	15 to 20 c.c.
Pure lithium carbonate	0.3 to 0.5 (gm.?)

The stain should be filtered. It colors intensely immediately after its preparation. The solution is very permanent, and is especially recommended for preparations hard to stain. It gives a gorgeous strawberry-red color, and stains sections in from one to three minutes. Differentiate the over-stained sections in hydrochloric acid alcohol, then put immediately into absolute (picric) alcohol.

Delage's Osmic Carmine.[19]—Take a strong solution of carmine in ammoniacal water and evaporate it on a water-bath, until the appearance of red clouds on the surface indicates that the excess of ammonia has disappeared. After cooling, add an equal volume of osmic acid (one per cent.) and filter under a bell-jar. A very dark fluid is thus obtained which has the staining properties of carmine, and the fixative properties of osmic acid. At the end of some days this reagent loses its odor and becomes darker. The fixative qualities have disappeared. It is best, therefore, to mix the acid and carmine solution at the time of using. This mixture is said to bring out more minute anatomical features than gold chloride.

Anilins.—Anilin [20] ($C_6H_5NH_2$) is a colorless oil boiling at 183° C., partly soluble in water (1 to 31), and acts as a strong base, forming well-crystallized salts with acids. The anilin oils of commerce are a mixture of anilin with ortho- and para-toluidin (Benedict). When mixtures of anilin and toluidin are heated together with certain oxidizing agents—such as arsenic, chloride of tin, mercuric chloride, etc.—among the various substances formed are two compounds named rosanilin and pararosanilin. The dyestuffs under the anilin colors are derivatives of these. Benedict divides them into three groups: *basic*, *acid*, and *neutral coloring matters*. In dyeing the *basic* are always used in the form of their salts *i.e.*, of their compounds with mineral or organic acids. They all contain nitrogen atoms, and it is to the presence of these that they owe their basic properties. The *acid* contain hydrogen atoms, which can easily be replaced by metals. They possess the property of combining with bases to form salts with the simultaneous evolution of water. The *neutral* are not numerous, the only example given by Benedict is artificial indigo obtained from propiolic acid.

The anilins are derived from coal-tar, and must be of the proper quality to be of any use in histology. Many are inconstant, and not to be depended upon for permanent results. Some are soluble in water, others in alcohol only, and one must be largely guided in his selection of a dye by the method in which the tissue has been treated. It is believed that the dyes are best fixed with benzole, and that by the use of this fluid there is a greater probability of the colors remaining permanent in Canada balsam. These dyes, as a rule, are not adapted to bulk staining. Very few of them give a precise nuclear stain by the *direct method*. Two of them, methyl green and Bismarck brown, are pre-eminently nuclear stains. Some of the others may be made so with fresh tissues by combining them with acetic acid.

The majority give a diffuse color, which in some few cases may result in a most precise and useful stain, by the *indirect* method—decolorizing.

Lee classifies these dyes according to their use for *direct* or *indirect* staining—the latter is also known as the "Flemming" method. With the *indirect* method it is necessary to get as *strong a solution as possible*, and the sections must be *very thoroughly* stained. Up to a certain point, the more the tissues are stained, the better do they resist the washing-out process, which is an advantage. Washing out is generally done with (ninety-five per cent.) alcohol, but it is well to *just rinse* the sections in water before bringing them into the alcohol. Clove oil will *extract more color* from the tissues, and it is therefore better to use some clearing medium, such as cedar oil, bergamot oil, xylol, etc., which does not attack the stain.

Victoria Blue.—The specimens fixed in "Flemming's mixture" for some hours are stained in a saturated aqueous solution of the dye. Wash in pure alcohol, clear in cedar or bergamot oil. It is a brilliant and useful nuclear stain. Chromatin and nuclei are colored blue. The cytoplasm is colorless if well washed out; if not, green or greenish blue. The "spongioplasm" is very finely brought out by this method. The reagent has a special affinity for elastic fibres. For this Lustgarten recommends an alcoholic solution diluted with from two to four parts of water. It is believed that fixation in some

chromic mixture is a necessary condition. Stain for a long time.

Safranin.—This is one of the most important of the anilin dyes, on account of its various degrees of electivity for nuclei and other constituent elements of different tissues, and for its superior permanence in balsam. It is exceedingly necessary to have a *good safranin*. With no other stains are there, perhaps, so many grades. It is, therefore, quite essential to procure the dye from some reliable source. Grübler (Leipzig, Germany) supplies only such as have been found by experiment with tissues to furnish the desired stain. Münder (Göttingen) also furnishes reliable dyes.

Babes's Solution:

Water	100 parts.
Anilin oil	2 parts.
Safranin to excess.	

The mixture should be warmed to from 60° to 80° C. and filtered through a wet filter. This solution will keep for a month or two.

Zwaardemaker's Solution.—This is obtained by making a mixture of about equal parts of alcoholic safranin solution and anilin water (anilin water is simply a saturated solution of anilin oil—pure anilin—in water); shake up the two and filter.

Cyanin (*Quinolein Blue, Chinolinblau*).—Cyanin should be dissolved in ninety per cent. alcohol and the solution diluted with an equal volume of water. (The dye must be dissolved in the alcohol, it will not dissolve in the dilute solution.) This stain colors fatty matters an intense blue. As it has powerful staining qualities, it should be used in very weak solutions. It is said that if tissues be stained slowly in very dilute aqueous solution of cyanin they may be mounted in balsam and a fairly precise and nuclear stain may be obtained. This dye is also useful for staining Infusoria, which under certain conditions it stains during life.

Congo Red [22] (*Congoroth*).—An "acid" dye, the aqueous solution, however, having a neutral or alkaline reaction. It becomes blue in the presence of the least trace of a free acid. (A test for the acidity of tissues.) It is a diffuse stain, but seems to be used chiefly in staining axis-cylinders.

Benzopurpurin.—Weak aqueous solutions should be used for staining, which is effected in a few minutes, then wash out with alcohol. Zschokke [22] says that *Benzopurpurin B.*, is the very best contrast stain to hematoxylin known to him, because it is not apparently affected by alcohol, or the usual clearing agents.

Deltapurpurin.—This is of a more purple red, having properties similar to those of Benzopurpurin, and may be used in the same way.

Benzoazurin.[23]—This dye is used in dilute aqueous solutions. The sections are over-stained and decolorized with one-half to one per cent. hydrochloric acid alcohol. If a nuclear stain is desired, the sections should be withdrawn when the celloidin has become bleached. If the tissue-elements are also to be stained, they should be taken from the acid alcohol a little earlier. A beautiful blue nuclear stain is obtained, which is quite as distinct and sharp as that given by hematoxylin or carmine. Two points are made for this dye: (1) that it stains very readily old alcoholic preparations; (2) that preparations containing picric acid are little or not at all affected.

Eosin (*Erythrosin, Primrose soluble, Pyrosin B., Rose B. à l'eau*).—Eosin is obtained by the action of bromine upon fluorescine, and is chiefly used as a contrast stain to hematoxylin. Lee suggests that a solution of eosin in anilin water might give results very different from those obtained from the ordinary solutions. Most preparations of eosin are soluble in both alcohol and water; some, however, are soluble only in alcohol.

Picric Acid.—This is very useful for secondary or ground staining in connection with hematoxylin and various carmine solutions. It has considerable power of washing out anilins, and great care must be used in this connection.

For Fresh Tissues.—*Methyl Green* (*Methylanilin Green, Vert Lumière, Lichtgrün, Grünpulver, Vert en Cristaux*).—A most excellent nuclear dye. It should be used in the form of a strong aqueous solution containing a little acetic acid (about one per cent.). The solutions *must* always be acid. Wash with water (may be slightly acidulated) and mount in some acid aqueous medium containing a little of the methyl green in solution. In the nucleus it stains nothing but the chromosomes or nuclein element, leaving the nucleoli, caryoplasm, and achromatic filaments untouched. Outside of the nucleus it stains some kinds of cytoplasm and some kinds of formed material, especially glandular secretions. Extranuclear structures are in general stained in some tone of blue-violet. Staining is instantaneous, over-staining never occurs. The solution is very penetrating, killing cells instantly without swelling or other change of form, and preserving their forms for at least some hours, so that it may be considered a delicate fixative. It is a most useful reagent in amyloid degeneration. "Undoubtedly methyl green is one of the most valuable stains yet known."

Schneider's Aceto-carmine.[24]—An old formula, but most admirably adapted for fresh tissues. To boiling forty-five per cent. acetic acid, add as much carmine as will dissolve. (Forty-five per cent. holds the greatest amount of carmine.) It may be used in a weak solution—diluted to one per cent.—or strong. The latter fixes and stains at the same time, and is very penetrating, a quality which renders it of much use where common reagents would often fail. The stain is a pure nuclear one.

Bismarck Brown (*Manchester Brown, Phenylin Brown, Vesuvin, La Phénicienne*).—The dye is not easily soluble in water. It may be boiled, and filtered after a day or two, or acetic acid added (the acid destroys the permanency of the stain), or alcoholic solutions may be used. A convenient form is the following:[25]

Bismarck brown	2 parts.
Alcohol	15 parts.
Distilled water	85 parts.

The solution gives a light oak tint and forms a pleasing contrast to safranin or hematoxylin. The mixture must be filtered often. The dye never over-stains and is rapid in its action. It is a fairly pure nuclear stain, and will work well either with fresh tissues or with such as have been hardened in chromic acid. It also possesses the property of staining cellular elements during life, but must be pure and neutral. For general purposes the addition of carbolic acid has been recommended.

Trinkler's Vegetable Stain.[26]—The stain is obtained by extracting the chlorophyll from the leaves of *Syringa vulgaris* by means of alcohol. After twenty-four hours the filtered extract is evaporated to dryness and the residue dissolved in water. The solution is of a dark-green color tinged with brown.

Double Staining.—*Genevan Reagent.*[27]—Under this name is recommended a double-staining reagent found useful in the differentiation of vegetable tissues. It consists of a slightly alcoholic and ammoniacal solution of Congo red (two per cent.) and chrysoidin (one-fifth per cent). The section is first decolorized by *eau de javelle* and then immersed in this reagent for a few seconds, when a beautiful double or triple staining is obtained.

New Method of Double Staining [28] (Pianese).—There is first prepared a saturated solution of nigrosin in a saturated solution of picric acid in alcohol (Martinotti's solution). Two parts of this solution and one part of anilin water are next mixed and allowed to evaporate in the open air. The crystals deposited from this are dissolved in absolute alcohol. From the latter solution are obtained cubical crystals of an olive-green color, soluble in water, alcohol, or ether. With these crystals is made a two per cent. solution in alcohol for tissues, in water for micro-organisms.

The sections are first stained with Beale's carmine or Orth's lithium carmine, and having been treated with acidulated alcohol are washed and dehydrated. They are now immersed from two to ten minutes in the alcoholic solution of picro-nigrosin, until they assume a brown hue. They are next decolorized in an alcoholic solution of oxalic acid, dehydrated, cleared, and mounted.

The nuclei are stained red ; the plasma, a dark yellow ; connective tissue, a pale green ; elastic fibres, violet, and cartilage yellow. If it is desirable to stain micro-organisms at the same time as the tissues, the sections are, after having been stained with carmine, decolorized by Gram's method, or by the Koch-Ehrlich method for tubercle bacilli, and then are immersed for five minutes in the aqueous solution of picro-nigrosin, and the process continued as above.

Kossinski's Safranin and Indigo Carmine.[29]—Stain the sections from ten to twenty minutes in a saturated aqueous solution of indigo-carmine, wash with water and with alcohol and stain with safranin (0.5 per cent. in dilute alcohol), dehydrate, and mount.

"Metallic" Stains.—The discussion of this group of stains will be limited to those applicable *par excellence* to the nervous system, and will be treated of under the head of staining nervous tissue, in conjunction with certain other stains.

"Intra Vitam" Stains.—A very few dyes possess the peculiar property of staining the cells of living tissue without any very evident impairment of their powers. They are cyanin, methyl blue, Bismarck brown, Congo red, and under certain conditions dahlia and gentian violet, and some others whose action is as yet insufficiently known.*

The dyes must be used in an extremely weak neutral or alkaline solution, Congo being an apparent exception in that it is among the "acid" anilins and may be used in quite strong solution. Of all these methyl blue has received the greatest amount of attention on account of its special affinity for the peripheral nerve-endings. This dye will also be treated of under stains for nervous tissue.

Staining Nervous Tissue.—*Impregnation.*—Ramón y Cajal's[30] modification of Golgi's short silver nitrate method. Small pieces of the brain or myel are fixed in the following solution :

Potassium bichromate	3 parts.
Osmic acid, one per cent.....	25 parts.
Distilled water.....	100 parts.

Use plenty of the solution and change at least twice during the first day, keeping in the dark. Embryonic or adult tissue may be used, the former giving perhaps the best results ; since the fibres are as yet deprived of their myeline, the silver is more readily deposited in them. It should be left in the solution from twenty-four to forty-eight hours. Older tissue should remain two or three days. The hardening process is of very great importance : if it is insufficient the silver later will form a granulous precipitate ; if the hardening be too great, the precipitate will not occur at all.

After hardening, the tissue is washed in 0.25 per cent. solution of silver nitrate for fifteen minutes. It is then brought into a 0.75 per cent. solution of silver nitrate, to which has been added a little formic acid in order to favor the reduction of the silver. For the best results some care must be used as to the amount of the acid used. Van Gehuchten recommends one drop to each 100 c.c. of the fluid.

The tissue may be left in this silver solution from thirty-six to forty-eight hours. A longer stay does not ruin it.

If the hardening is of the proper degree, the silver nitrate will be deposited with extraordinary fineness in the nerve protoplasm as silver bichromate. The process thus far should have been carried on in the dark.

Kölliker recommends placing in forty per cent. alcohol before cutting free-hand, or better dehydrate in one hundred per cent. alcohol for one hour, then in celloidin one hour, and after an hour or two of hardening cut in the microtome. Put sections in creasote for a quarter of an hour, then in turpentine, and mount in xylol balsam without cover-glass. It is desirable that the imbedding process should be as short as possible. Van Gehuchten[31] transfers the specimens from the silver bath directly to strong alcohol, where they are left from fifteen to twenty minutes, then about a quarter of an hour in absolute alcohol. They are left about the same length of time in a solution of celloidin, then fastened to a holder and put into seventy per cent. alcohol to harden.

According to this process, sections can be cut in about an hour from the time the specimen has left the silver solution.

On account of the difficulty of obtaining successful silver precipitates in the sympathetic nervous system by the ordinary method, Ramón has suggested that double or even triple impregnations be made by re-immersing the tissue in the osmium-bichromate mixture, after it has passed through the silver baths. The reaction is said to be much more constant.

If a cover-glass be placed upon the balsam while it is yet soft, the sections soon become blurred or decolorized, the supposed reason being the irregular drying of the balsam causing a diffusion stream that carries off the silver precipitate. Greppin[32] uses hydrobromic acid to prevent this. As recommended by Ramón y Cajal, it is well to put the slides after mounting in an oven heated to about 40° C., so that the balsam may dry as rapidly as possible. Huber[33] employs a cover-glass after the following manipulation : The sections are mounted in turpentine balsam. The slide is held over a flame and gradually heated to avoid the formation of air-bubbles and to drive off the turpentine vapor, until the balsam is so thick that when cooled it becomes hard immediately. On the hot balsam a heated cover-glass is now lightly dropped and the preparation is said to remain durable.

Martinotti[34] has recommended the addition of five per cent. glycerine to the silver solution as favoring the reaction with the ganglionic cells and their nervous prolongations, and for obtaining preparations of extreme *délicatesse*. To prevent surface precipitates, he uses a pap of blotting-paper prepared in distilled water.

The silver method[35] colors deep black the nerve-cells with their protoplasmic processes and all non-medullated nerve-fibres, the neuroglia cells and their extensions a reddish-brown, while the vessels assume more of a reddish cast. At times certain lymph-spaces and a few medullated nerve-fibres are also colored. It is not yet settled whether the coloration depends upon an impregnation of the cell-bodies with the silver salt, or if it is simply an incrustation. Golgi, Ramón y Cajal, and Kölliker hold to the first idea ; it is only certain that with the non-medullated fibres it is an impregnation. The order in which the parts color most readily is as follows : the nerve-fibres, the protoplasmic processes, the nerve-cell bodies, the neuroglia cells, and the blood-vessels.

Golgi's Sublimate Method.[36]—An old but useful method. Very briefly, it consists of hardening the nervous tissue for fifteen or twenty days in potassium bichromate, and then passing it directly over to 0.25 or 0.50 per cent. solution of mercuric chloride. This is renewed as often as it becomes yellow, and the tissue should remain in the mercuric solution at least ten days. A longer stay will probably improve the results. The sections should be cut on a freezing microtome, and afterward thoroughly washed in water to avoid the formation of a black precipitate. They are best preserved by mounting in glycerin. The method is useful in demonstrating the nerve-cells with their processes, also the nuclei, and sometimes the blood-vessels.

The sublimate seems to be more limited than the silver nitrate method, as the more favorable results are obtained only from the cerebral cortex.

Signor Tal[37] modifies the above method by after-treatment with sodium sulphide. The mercury is changed into sulphide and the preparations become blackened ; the tissue that has not undergone the influence of this reaction is stained with a solution of Magdala red. The silver method is also said to be improved by this after-treatment with the sulphide.

Magini[38] recommends the substitution of zinc chloride in 0.5 to 1 per cent. solution for the sublimate. Sections are washed quickly in alcohol, imperfectly cleared with creasote, and mounted in damar.

The process is said to demonstrate better than Golgi's

* For a fuller discussion of this question, see Martinotti's paper, Zeit. f. Wiss. Mik., v., 305 (1888).

the finer structure of ganglion cells and their processes.

Cox's Sublimate Impregnation.[39]—The hardening and impregnating fluids are combined and allowed to act together for two or three months.

The mixture is as follows:

Five per cent. potassium bichromate.. 20 parts.
Five per cent. mercuric chloride..... 20 parts.
Five per cent. potassium chromate.... 16 parts.
Distilled water.....30 to 40 parts.

The reaction of the fluid should be as slightly acid as possible. The preparations are not permanent under a cover-glass in Canada balsam or damar, on account of the acidity of the medium or some other unknown cause. The sections must be cut in a freezing microtome. They are placed for an hour or two in a five per cent. solution of sodium carbonate, washed in water, placed for a short time in absolute alcohol, then in some oil, and finally covered with some rapidly drying resin [sandarac ?].

If they must be covered with a glass, the resinous layer should be allowed to dry and then covered with castor-oil. Then the cover-glass is put on and squeezed down so as to squeeze out the superfluous oil, or by using styrax, or a mixture of gum arabic and water, etc., the preparations may be kept intact under a cover-glass.

Obregia's Gold Modification of Golgi's Methods.[40]—The sections are transferred from absolute alcohol to the following solution:

Gold chloride, one per cent.....8 to 10 drops.
Absolute alcohol..... 10 c.c.

This should be made half an hour previous to use and exposed to diffuse light. When the sections are put into it, the containing vessel should be placed in the dark. In from fifteen to thirty seconds or longer the silver is gradually replaced by the gold, or the mercury changed into gold amalgam. The sections are quickly washed, first in fifty per cent. alcohol, then in distilled water, and finally in a ten per cent. solution of hyposulphite of soda for ten or fifteen minutes, and then washed in distilled water thoroughly. Too long an immersion bleaches so that the finer fibres disappear. The sections, after the proper degree of toning, may be stained as desired (Weigert's, alum carmine, etc.), and mounted in Canada balsam with cover.

Paladino's Palladium Chloride Method.[41]—Small pieces, 5 mm. thick, of the neuraxis, previously hardened in bichromate or sublimate, are left for two or three days in a one-tenth per cent. solution of palladium chloride, a trace of hydrochloric acid being added to insure the complete solution of the salt. The pieces are then transferred to a four per cent. solution of potassium iodide and left for an hour or two, then dehydrated and imbedded in paraffine. The paraffine is removed by xylol and the sections mounted in balsam. The reaction is favored by keeping in a dark place. The method is also applicable to the peripheral nervous system, and demonstrates the axis-cylinders particularly well.

Monti's Copper Method.[42]—Small pieces of nervous tissue are hardened in two to three per cent. bichromate or Müller's fluid, until they become quite firm. They are then immersed in a mixture of equal parts of a solution of copper sulphate and Müller's fluid. The reaction takes place after twenty-four hours. The stained elements appear of a blackish-yellow color in transmitted light, and of a reddish color in direct light. The reaction has been obtained in the small nerve-cells of the cortex and of the cerebral ganglia, in the small nerve-cells of the molecular layer of the cerebellum, and in the cells of the olfactory bulb, and in the fibres and neuroglia cells.

Berkley's Osmium-Copper-Hematoxylin Stain.[43]—A rapid Weigert method. Small pieces of the cerebrum, cerebellum, or myel, not more then 2.5 mm. thick, are fixed in Flemming's solution from twenty-four to thirty hours, in a temperature of 25° C., and then without washing transferred directly to absolute alcohol, which is changed twice during the following twenty-four hours, then placed from twelve to twenty-four hours in celloidin.

The knife must be well moistened with alcohol, and the sections must be very thin. They are washed in water and then brought into a saturated solution of copper acetate, and allowed to stand overnight in a small covered vessel; or, if it is desirable to expedite matters, the vessel containing the sections may be put on a water-bath and heated to a temperature of 35° to 40° C. for twenty-five to thirty minutes, and the copper solution allowed to cool.

The sections are washed again in water for a very short time, and finally carried into a hematoxylin solution which is prepared as follows: 50 c.c. of distilled water are boiled thoroughly for a few minutes in a flask and 2 c.c. of a saturated solution of lithium carbonate added; allow the boiling to continue a minute longer, and then add 1.5 to 2 c.c. of a ten per cent. solution of hematoxylin in absolute alcohol. The flask is then shaken and corked, and placed aside to cool. It is better to prepare small quantities of the solution as needed, since it deteriorates somewhat. The solution can be used at once, but it is better to allow it to stand for a day. After staining, the sections are thoroughly washed and put into Weigert's differentiating fluid of borax and potassium ferrocyanide, which may be diluted one-third with water. This decolorizing is an important part of the process. It is necessary that the fluid should penetrate the tissue quickly and that its action be not too long continued, otherwise a number of the finest medullated fibres will become decolorized. Usually one to three minutes are sufficient for the purpose. After decolorizing, wash the sections two or three times in water, then in alcohol, bergamot oil, and mount in xylol balsam. Sections prepared according to the above method should be of a blackish-brown color; the differentiation between white and gray substance is as clearly seen as with Weigert's method. Under the microscope the medullated fibres should appear blue-black-brown, the glia-substance yellow, and the nerve-cells colorless; or in case the chrome salts have not been completely reduced, some or all cells with their processes appear of a brownish-black color.

Ziehen's Method.[44]—The pieces of nervous tissue are to be placed for five weeks in a mixture of equal parts of one per cent. chloride of gold and one per cent. corrosive sublimate. The pieces are then sectioned in dilute lugol (one-quarter per cent.) solution. The medullated or non-medullated fibres, the nerve-cells, and the neuroglia cells are colored blue. In the ganglion cells the nucleus and nucleolus are clearly differentiated.

Benda's Picric Acid Method.[79]—Small pieces of nervous tissue are placed for two or three days or longer in a saturated aqueous solution of picric acid, washed in water, and the hardening continued in alcohol. Paraffine is preferred for imbedding, celloidin not giving good results. The sections are made as thin as possible and placed for some hours in a concentrated solution of iron sulphate (mordant); after careful and repeated washings they are transferred to a one per cent. aqueous solution of hematoxylin until they become of a deep-black color (about ten minutes). They are then bleached for about five minutes in chromic acid (1 to 2,000), washed well in water, dehydrated, and mounted in balsam. It is stated that not only are the fibres but the intimate structure of the ganglion cells made evident.

Upson's Gold Method for Axis-Cylinders and Nerve-Cells.[45]—Pieces of the neuraxis are hardened in the dark for four to six months in potassium bichromate, beginning with one per cent. and increasing to two and one-half per cent. Wash in water and complete the hardening by putting into fifty per cent. alcohol for the first two or three days, ending with ninety-five per cent. until the pieces are of a greenish color. Sections may be made with or without imbedding, but must be thoroughly dehydrated before proceeding. First method: Place the section for one or two hours in a one per cent. gold chloride solution to which two per cent. hydrochloric acid has been added. Wash in distilled water, transfer on platinum or paper lifter to the following solution:

Ten per cent. solution potash..... 5 c.c.
Ferricyanide of potassium..... a trace.

Wash in this for half a minute, then thoroughly in distilled water, and transfer to the following:

Acid. sulfurosum	5 c.c.
Tinct. iodi (three per cent.)	10 to 15 drops.
Mix and add liq. ferri chloridi	1 drop.

Let the section remain in this until it assumes a rose color. It is then washed thoroughly in distilled water, dehydrated in absolute alcohol, oil of cloves, and balsam.

Second Method: The section is immersed for two hours in the following solution:

One per cent. chloride of gold	5 c.c.
Ammonium vanadicum (sat. sol.)	10 drops.
Acid. hydrochlor.	3 drops.

After washing in distilled water it is immersed from thirty to sixty seconds in the following:

Ten per cent. caustic potash	5 c.c.
Ammonium vanadicum	a trace.
Ten per cent. permanganate of potash	10 drops.

The section is again washed and put in the following fluid:

Tin solution	15 drops.
Distilled water	3 c.c.
Iron solution	3 to 5 drops.
Acid. sulfurosum	3 c.c.

The tin solution is obtained by adding chloride of tin to three per cent. tincture of iodine, until the color becomes white or yellowish. The iron solution is a saturated solution of ferrum phosphoricum in distilled water. When the section has become red it is treated as in the first method. It is said that the results are splendid.

Marchi's Solution:[46]

Müller's fluid	2 parts.
One per cent. osmic acid	1 part.

Of great value in pathology in staining nerve-fibres in the earlier stages of degeneration, before sclerosis sets in (especially a few days after the establishment of a lesion). The degenerated medullated fibres are stained black while the rest remains almost uncolored. It is better to put thin pieces of the brain or myel into a large quantity of the solution (after previous hardening for ten days in Müller's fluid), and to leave them in it for a week or more; sections can also be stained by immersing in the above solution for a few hours. The further process is, as usual, mounting in Canada balsam.

Weigert's Method without Decolorizing.—The tissue is hardened in Müller's fluid and treated in the usual way with eighty-five per cent. alcohol, and then an equal length of time in absolute alcohol; then it is transferred to celloidin and finally imbedded. An important part of the process is the coppering. The imbedded pieces are allowed to remain for twenty-four hours in a mixture of equal parts of a seven per cent. to ten per cent. solution of sodium tartrate and a cold saturated solution of copper acetate, which is kept at an equable temperature of 38° to 40° C. They are then transferred to a mixture of equal parts distilled water and saturated solution of copper acetate for twenty-four hours, also in the incubator. The pieces may then remain in eighty per cent. alcohol until cut. The sections must be very thin to produce a sharp differentiation.

The staining fluid is composed of one part of the ordinary alcoholic hematoxylin solution (one to ten), as used for the old method, and nine parts of an aqueous solution of lithium carbonate. This mixture should be prepared as needed. The sections remain in the stain from four to twelve hours. They are then thoroughly washed in distilled water, dehydrated in ninety per cent. alcohol and cleared, first in anilin-xylol (two to one), and afterward in clear xylol, and mounted in xylol balsam. Care must be taken to employ the best balsam, otherwise the color will gradually fade from the specimens. If it is desirable to have the ground-work particularly light, the preparations can be washed in a very weak solution of acetic acid (⅛ per cent. to ½ per cent.), but a longer stay in distilled water usually suffices. The advantages claimed for this method are, that it dispenses with the tedious process of differentiation, and brings out more distinctly than the old method the finest medullated fibres, and the distinction between these fibres and the cells and other components of the tissue is more plainly marked.

It is said that Weigert's ordinary method can also be usefully applied to lymphatic glands and skin.

Hill's Modification of Weigert's Method.[15]—The object of the method is to render the nerve-cells and non-medullated fibres susceptible to the stain by previous treatment with carmine alum, or simply an alum solution. For good results the following process must be rigidly carried out: (1) Pieces of brain or myel are placed in a two per cent. to a two and one-half per cent. solution of potassium bichromate for six weeks. (2) The bichromate is washed out with an abundance of thirty per cent. alcohol, changed daily until no further color comes from the tissue. (3) The hardening of the tissue is completed in strong alcohol. (4) Pieces of convenient size are placed in water to remove the alcohol, and then for two days in a solution of carmine alum, prepared as follows: Place in a shallow dish carmine, potash alum, and distilled water. Boil for three hours, restoring the water to its original level from time to time as it evaporates. Both carmine and alum should be *in excess*. When cold the solution is decanted and filtered. (5) The tissue is then cut and the sections placed for twenty-four hours in a half-saturated solution of copper acetate. (6) The sections are then placed in the hematoxylin for eight hours at a temperature of about 40° C. (7) Decolorize to exactly the right degree in Weigert's bleaching solution diluted with an equal volume of water. It is safe to assume that the matrix of the tissue and the celloidin are decolorized at the same time.

Vasale's Modification of Weigert's Method.[9]—Three solutions are required: (1) Hematoxylin, one gm., dissolved in one hundred gms. of water by the aid of heat. (2) A saturated filtered solution of neutral acetate of copper.

(3) Borax	2 gms.
Ferricyanide of potassium	2.5 gms.
Water	300 gms.

The sections are removed from alcohol to solution (1) for three to five minutes, then for same length of time in solution (2), whereon they become black. They are washed quickly in water, and transferred to solution (3), wherein the ganglion cells, the neuroglia and degenerated parts are quickly decolorized, the medullated fibres remaining of a dark-violet color. Finally, the sections are washed thoroughly in water, dehydrated in absolute alcohol, cleared in carbol-xylol (three parts xylol to one part carbolic acid) and mounted in balsam. Alum or picro-carmine or Pal's method are recommended if a contrast stain is desired.

Mallory's Phospho-molybdic Acid Hematoxylin:[48]

Ten per cent. solution of phospho-molybdic acid	1 part.
Hematoxylin crystals	1 part.
Water	100 parts.
Chloral hydrate	6 to 10 parts.

Let the solution ripen for a week exposed to the sunlight. Filter before using; it can be used repeatedly. The sections stain in from ten minutes to an hour. Wash out in forty per cent. to fifty per cent. alcohol, changing two or three times. The celloidin becomes perfectly colorless. Then dehydrate and mount as usual. The best results are perhaps obtained by staining rather deeply for about thirty minutes and washing out thoroughly for thirty minutes or an hour. The ganglion cells and their processes, axis-cylinders, and neuroglia (seen especially well around the central canal of the myel) are all sharply stained of a deep blue color. If the specimens are left too long in the alcohol they lose their sharpness and clearness of detail. The staining fluid must be kept free from alcohol. The chloral hydrate retards deterioration. If the solution does not stain deeply enough, add a little more hematoxylin (Fig. 272).

Kultschitzky's Hematoxylin.[7]—Simpler than Weigert's. Pieces of brain or cord are hardened in Müller's or Erlicki's fluid and imbedded in celloidin. The sections are then placed in the following solution:

Hematoxylin (dissolved in a little alcohol)	1 gm.
Sat. aqueous sol. of boracic acid	20 c.c.
Distilled water	20 c.c.

A little acetic acid is added before using (two or three drops to a watchglassful). The sections should stain some few hours. The medullated nerve-fibres are stained blue, the rest of the tissue yellow or yellowish-red. If the sections are then placed for twenty-four hours in a saturated aqueous solution of carbonate of sodium or lithium, the nerve-fibres become dark blue, while all the rest becomes almost uncolored. Then pass through alcohol and mount in balsam.

A still more simple hematoxylin solution which is said to give the same result is :

Two per cent. acetic acid	100 c.c.
Hematoxylin (dissolved in a little alcohol)	1 gm.

Schmaus's Stains for the Axis-Cylinder in Sections of the Spinal Cord.[49]—Gierke's method is modified as follows : After previous hardening of the tissue in Müller's fluid, the sections are stained in the following solution :

Carminate of soda	1.0 gm.
Nitrate of uranium	0.5 gm.
Water	100.0 c.c.

The solution is heated for half an hour and filtered when cold. The sections are left in the fluid for fifteen to twenty minutes, and then washed in water. The axis-cylinders take the stain well, leaving the celloidin unaffected.

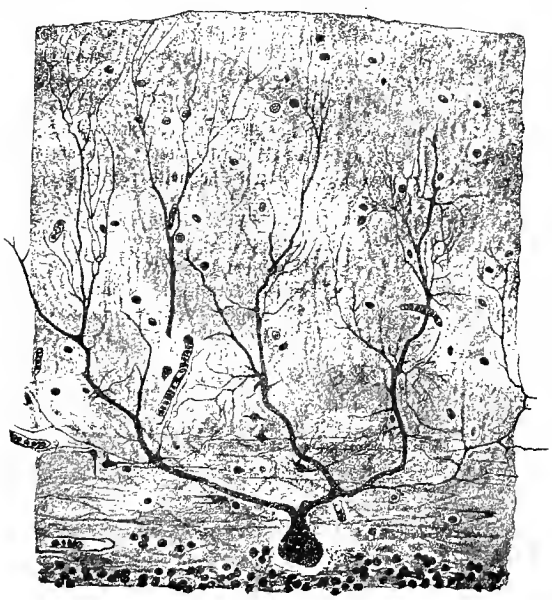

FIG. 272.—Purkinje's Cell.

Another method is to stain the axis-cylinders with English blue-black. The solution consists of one-quarter per cent. blue-black in fifty per cent. alcohol, with a little picric acid added. After an immersion of one hour the sections are washed and mounted.

Sig. C. Negro[50] has recommended a stain for the demonstration of the motor nerve-endings in striated muscle. It is practically Delafield's hematoxylin with some of the proportions slightly changed. The preparations are teased out on a slide, stained, washed, and mounted in a mixture of equal parts of glycerin and water.

Apáthy's method[29] for differentiating nervous and connective tissues consists of staining with Heidenhain's hematoxylin, and after-staining with very weak alum hematoxylin.

Methyl Blue.—Since the introduction of methyl blue as a staining agent for *living* tissue by Ehrlich[51] in 1885, with its special affinity for the peripheral nervous system, and the sensory fibres in particular, many new and important contributions have been given to science. It was at first believed that only the axis-cylinders of the sensory fibres took the stain. Arnstein[52] found in 1887 that the motor nerves and other elements stain as well, but later. The stain has already cleared up many doubtful points, and promises a solution to the nerve-ending problem. Useful as is Golgi's method in this connection, the methyl blue is in some ways superior to it. The stain seems to be more favorably adapted to the lower forms (cold-blooded). Mammals and birds soon die after the injection, and a true *intra vitam* reaction is not easily obtained.

The living tissue soon throws off the color unless some restraining agent is used. Iodine, picro-carmine, corrosive sublimate or picrate of ammonia may be used for this purpose. Various methods are employed with greater or less success. That of Professor S. Mayer[29] is among the recent ones, and probably as successful as any. The process consists essentially of two parts : first, the staining of the tissue, and second, the fixation of the stain. The staining solution is made by dissolving one gm. of the methyl blue in 300 to 400 c.c. of a one-half per cent. salt solution. The "fixing" solution is composed of a cold saturated solution of picrate of ammonia diluted with an equal volume of pure glycerin. The staining fluid is injected into a blood-vessel of the animal, or pieces of the fresh tissue are soaked in the fluid, or the animal itself immersed in the solution without immediate danger to life. The amount injected varies with the size of the animal. Six to eight cubic centimetres[47] are generally sufficient for a frog, the coloring usually taking place in from one to three hours. Small pieces of the object are immersed in the picro-glycerin, and are at once ready for examination. If suitable for a permanent preparation, the cover can be fastened down with a mass composed of equal parts of wax and resin. The picro-glycerin changes the color, all shades of red, brown, and black being seen in the axis-cylinders and the non-medullated terminal nerve-expansions. This is compensated for by the clearing up of the preparation and the permanency of the stain. The method is simple and rapid. Small pieces, as fresh as possible, are placed for about ten minutes in the methyl blue solution; they are then well washed in a one-half per cent. solution of salt and examined at once in the picro-glycerin ; the operation being complete in about thirty minutes.

Professor A. S. Dogiel[9] has found that the addition of osmic acid to the picrate of ammonia solution is attended with several advantages, in that it hardens the tissue just a little and stains the medullary sheath of nerves black. The solution is made by adding 1 or 2 c.c. of a one per cent. osmic acid solution to 100 c.c. of a saturated aqueous solution of ammonium picrate. The stain is fixed by immersing the preparation in this mixture from eighteen to twenty-four hours. It is then transferred to glycerin diluted with an equal volume of water, in which the color of the nerves will keep for a long time. If it is desirable to render the object firmer for sectioning, a stronger solution may be used as follows :

Picrate of ammonia (sat. sol.)	25 to 30 c.c.
One per cent. osmic acid	1 to 2 c.c.

The specimen remains in this for twenty-four hours, after which it may be imbedded in elder pith, liver, etc., and sectioned.

Parker's Method of Imbedding Methyl Blue Preparations in Paraffine.[53]—A concentrated aqueous solution of corrosive sublimate was found to be the best fixative for the stain. The object was left in this for about ten minutes. It was then dehydrated for fifteen minutes in solution (A) made as follows :

Methylal	5 c.c.
Corrosive sublimate	1 gm.

The next step is to remove the sublimate and replace gradually the methylal by xylol. To accomplish this the object is put for ten minutes into the following solution (B) :

Methylal	1 vol.
Solution A	1 vol.
Xylol	2 vols.

It is then transferred to an abundance of xylol for four or five days, and then it may be mounted as a transparent specimen in xylol balsam, or imbedded in paraffine

and cut in the usual manner. The sections should be fixed to the slide with Schällibaum's collodion. Mayer's albumen discharges the color. It is said that after an interval of a month the finer details of the specimen are likely to fade.

Blood. *Biondi's Method.*—The aim has been to find a method which would preserve the morphological elements intact by means of good *fixation, preservation, imbedding, and mounting*, or to treat blood as a solid tissue. The process is equally useful in the study of other fluid tissues, and has been successfully applied to the study of the maturation of the spermatozoa, and, as suggested by the originator, may doubtless be used to advantage in the study of the Infusoria. The material used for imbedding is *agar*, the columnar form (*Säulen Agar*) is considered the best. Long and explicit directions are given for the preparation of it, which may be consulted in Biondi's paper in the *Archiv für Mikroskopische Anatomie*, vol. xxxi., p. 103 (1887), or in an abstract of the paper published in the *American Naturalist*, vol. xxii., p. 379 (1888). The essential points are to get a very clear preparation and to keep it *sterile* until used.

By the aid of a pipette blood is taken from the heart of a frog, and two drops of it allowed to fall into 5 c.c. of two per cent. osmic acid. Shake immediately in order to scatter the corpuscles; after standing a few minutes the corpuscles will sink to the bottom of the vial, the deeper layer being formed mainly of the red ones, since their specific gravity is greater. They are left in the acid from one to twenty-four hours. When fixed, four to five drops of the mixture are dropped into the melted agar. By rotating the tube the corpuscles are distributed through the agar, the whole mass is poured into a paper box (as in paraffin) and allowed to stiffen. It is put into eighty-five per cent. alcohol for hardening, where it remains from three to six days, until it becomes hard enough to section, when it may be enclosed in elder pith and cut; or if finer sections are desired, the block of agar is transferred from the eighty-five per cent. alcohol to oil of bergamot for twenty-four hours, then direct to soft paraffine kept at a temperature of 45° C. After one or two hours the process may be completed in the usual way. The paraffin saturates the block, and the sections may be freed from the paraffin by the usual solvents and then stained. Almost any stain is suitable. Methyl green, methyl blue, fuchsin, and safranin, are mentioned as giving very reliable results. The agar itself does not stain, except with the most intense anilins (*e.g.*, gentian violet), but may be most easily decolorized with alcohol or any other bleaching fluid. The sections may be cleared in the ordinary clearing reagents except xylol, which causes the sections to curl. Mount in balsam or damar.

Auerbach's Method for Amphibian Red Blood Corpuscles.[54]—It is claimed that the corpuscles are invested with a colorless membrane. By allowing a drop of blood, carefully protected from loss of fluid, to stand for some hours, the substance of the corpuscle after a time recedes from the membrane, and the addition of a little physiological salt solution causes the membrane to swell up like a bladder. Hardening in a saturated picric acid solution and subsequent washing with water is said to demonstrate this still better. If such a preparation be stained with eosin and anilin blue, the membrane takes on the blue stain, and the adjacent layer the red. The membrane can be made to swell up and burst, allowing the contents to escape, leaving the empty sac behind, by treating with 0.1 per cent. to 0.25 per cent. solution of sublimate, one per cent. solution of boracic acid, one per cent. sodium chloride, or two per cent. to ten per cent. chromate of ammonia. Two parts are noted in the cell-body, a cortical and a medullary substance. The cortical portion in unstained sublimate preparations appears of a structureless homogeneous substance, colored reddish-yellow by the hæmoglobin. It is said to contain all the hæmoglobin of the corpuscle. This cortical or hæmoglobin layer also has a peculiar contractility, which causes a wrinkling of the surface.

In picric acid preparations, the cortex shows a very beautiful network, an unnatural condition due to the formation of vacuoles.

The medullary substance is colorless. In sublimate preparations dark granules appear scattered about. In picric preparations it appears clear like a large hole. In the nucleus are imbedded several nucleoli. In *Rana* from eight to sixteen are found, in the Urodeles still more, and in *Triton tæniatus* as many as forty. In the Urodeles their diameter is from 1.2 to 2 μ. As a rule, they are not connected with each other, so they do not form the junction-points of a network. In the adult animal these nucleoli usually stain blue; hence they are termed cyanophilous. In the larval condition a few of them will stain red (erythrophilous); while at a still earlier stage, there is but a single large nucleolus composed of both substances.

Gage's Method of Demonstrating Fibrin Filaments.[55]—A drop of fresh blood is placed on a cover-glass or slide, arranged as in B or C, Fig. 273. The preparations are then put into the moist chamber A to prevent drying. After ten to thirty minutes a drop of water is drawn around the edge of the cover, which is then raised, the fibrin generally adhering to it. The specimen is thoroughly washed in normal salt solution or water, and stained for three or four minutes in an aqueous solution of hematoxylin, followed by eosin for one minute. Wash and set the preparation on edge to dry spontaneously. When dry it is put over a shallow cell of some good cement. Thorough dryness is very necessary.

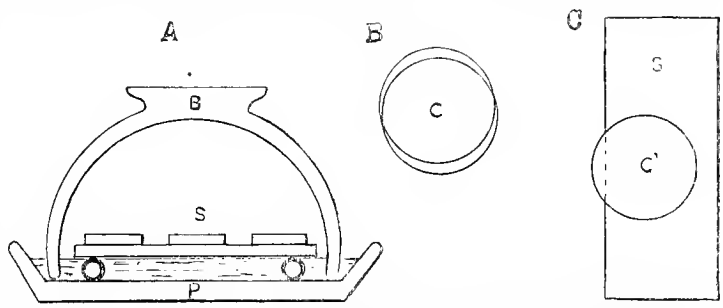

Fig. 273.—Fibrin Apparatus. *A*, Simple Moist Chamber; B, bowl serving as bell-jar; P, plate containing water; S, slides holding the preparations. They rest upon a bench made by cementing short pieces of large glass tubing to a strip of glass of the desired length and width.
B, Cover-glasses, made Eccentric (C) for more Convenient Manipulation.
C, Slide (S) with Projecting Cover-glass (C), so arranged in order to prevent the folding of the fibrin when the cover-glass is raised.

The network is much coarser in mammalian blood or lymph than in that of a cold-blooded animal, *e.g.*, frog or necturus. With the latter it is necessary to work with the greatest rapidity, as coagulation occurs much more quickly than in mammals.

Watase's Method for Differentiating Sexual Cells.—The following modification is adopted by Watase from Auerbach. The sexual cells, either in the testes, ovary, or in the hermaphroditic gland, where both male and female cells often exist side by side, are killed in Auerbach's fluid, or simply in a saturated aqueous solution of corrosive sublimate, and cut in paraffin in the ordinary way. Use Mayer's albumen, or better still, dilute alcohol or distilled water for fixing the sections to the slide, as the latter bias the tissue least for staining. Make a standard solution (A) of anilin water by dissolving anilin oil in water. Add enough alcohol to make a twenty per cent. solution.

For a blue stain (B) take:

Cyanin B. B.	1 gm.
Standard solution (A)	100 c.c.

For a red stain (C):

Chromotrop R. R.	1 gm.
Standard solution (A)	100 c.c.

A more powerful red stain (D) is as follows :

Erythrosin..... 1 gm.
Standard solution (A)..... 100 c.c.

For contrast staining it is immaterial which solution, (B) or (C), is used first.

If solution (D) is employed it should be used before the blue. The sections stain very quickly. Wash in fifty per cent. alcohol and proceed as usual. The anilin colors above mentioned may be used either in alcoholic or in aqueous solution without the anilin oil.

The nucleus of the ovum takes on a red color, while that of the spermatozoon becomes blue, indicating that the nuclear substance of the female cell is *erythrophilous* (Auerbach) ; that of the male, *cyanophilous* (Auerbach).

Different stages in the development of the spermatozoon, as in mammals, are indicated by different tones of color. At the beginning (spermatogonium stage) the color is *violet*, probably due to a mixture of the blue and red ; at the next stage (spermatocyte) the color is decidedly *green*, with one or two erythrophilous nucleoli ; another stage (spermatide) is *greenish-blue*, and the final (spermatozoon) is a *deep blue*. Sexual differentiation has been successfully demonstrated by Auerbach, Balbiani, and Ryder, but with different methods. Dr. Watase has succeeded in differentiating the sexual cells in the following animals : asterias, unio, limax, loligo, necturus, diemyctylus, rana, bufo, tortoise, fowl, mouse, rabbit, cat, dog, and man. He has also very recently obtained successful results in the sexual cells of Tunicates, by the use of the Biondi-Erlich triple mixture (aqueous solution).

The Permanent Preservation of Caustic Potash and Nitric Acid Preparations.—It was found that thirty per cent. to fifty per cent. aqueous solutions of caustic potash act with great rapidity upon intercellular substance, but quite slowly on cellular elements. Weak solutions dissolve all the elements quite rapidly. The action of the strong solutions can be checked at any time by means of a sixty per cent. solution of potassium acetate, or by the addition of enough glacial acetic acid to neutralize the caustic potash and form acetate of potash.

Perfectly fresh tissue should be used, but should not exceed half a cubic centimetre in size, and fifteen to twenty times as much potash should be taken. When the elements separate readily, the caustic potash is poured off and replaced by an abundant supply of a sixty per cent. solution of acetate of potash, to which one per cent. glacial acetic acid may be added. The isolated elements can be mounted in acetate of potash, glycerin, or glycerin-jelly. If staining is desirable the tissue, after removal from the acetate of potash, is washed thoroughly in water. It can then be colored with hematoxylin or alum carmine.

Nitric acid is used in a twenty per cent. aqueous solution ; the length of treatment varies with the temperature ; ordinarily one to three days are required. If heat be judiciously applied it may be completed in a few minutes. The acid is thoroughly washed out with water. Put the tissue into the following solution :

Saturated aqueous solution of alum ... 100 c.c.
Chloral hydrate..... 2 gms.

The nuclei are then stainable in aqueous hematoxylin. After the usual processes the preparations are mounted in glycerin jelly or balsam.

Imbedding Methods.—The *raison d'être* of imbedding is to fill up the interstices as well as the tissues themselves, with a more or less firm material, in order that the specimen may be cut without being torn or distorted. This is the end aimed at by all infiltration methods. Practically, there are two methods now in vogue : paraffin and collodion (celloidin). Each has many ardent adherents, and each in some way possesses advantages over the other. Paraffin requires heat ; sections of very large objects are likely to split, and are necessarily rather thick. With small objects much thinner sections can be cut than with collodion ; the adhering of the sections to each other in the form of ribbons is very convenient for serial work. With collodion heat is unnecessary. It is a cleaner and perhaps shorter method than with paraffin, but except for large objects, the sections under the most favorable conditions are thicker than by the paraffin method.

A safe rule to follow is to use paraffin for small objects, collodion for large, or where very thin sections are not so essential. These methods are so extensively employed that any detailed description is obviously out of place here, and what follows will be strictly limited to some of the various modifications that have been suggested within the last few years.

Lee withdraws his preference, except for small and easily penetrable objects, from chloroform as a clearing and infiltrating medium for specimens before going into paraffin. He finds it deficient in penetrating power for large objects, and somewhat tedious to remove before putting the specimen into pure paraffin. Cedar-wood oil is found preferable, as it penetrates rapidly ; preserves delicate structures ; mixes readily with paraffin, and does not make tissues brittle though they may be kept weeks or months in it.

Przewoski's Method.[57]—As a safer, more economical, and more easily applied method than absolute alcohol, this writer recommends that the object be transferred from ordinary alcohol to anilin oil, and left there for at least twenty-four hours. It is then wiped, and the anilin oil removed by soaking in chloroform for twenty-four hours. It is then immersed in chloroform paraffin (forty per cent.), and the next day in melted paraffin, which must be cooled down as soon as possible to prevent its becoming brittle. The anilin oil may be previously dehydrated by distillation, or by dropping therein a piece of caustic potash.

It is doubtful if this method possesses any real advantage over that proposed by Lee. If the cedar-oil has the merit claimed for it, the above process might be abridged by transferring the object from the anilin-oil to the cedar-oil, and then direct to paraffin.

Paraffin Infiltration by Exhaustion.—Mr. A. Pringle states that this method is of great value in ordinary work. The preparation in melted paraffin is placed in an air-pump and the pumping continued as long as the air-bubbles arise. The paraffin is to be kept melted the whole time. The advantages claimed are : "great celerity, certain and complete infiltration, certain removal of the solvent, absence of distortion of the tissue-elements, obviation of necessity for prolonged heating of the objects, possibility of using the same paraffin over again, pecuniary economy." Preference is given to chloroform infiltration.

The rolling up of paraffin sections is often a source of great annoyance to the biologist. It is said that after the removal of the paraffin by turpentine or benzine, the sections, if brought into concentrated carbolic acid, will unroll themselves safely and float on the surface of the liquid.

Fixation of Sections to the Slide. *Method for Fixing and Flattening Paraffin Sections.*[59]—The sections are placed on a dry slide or are moistened with seventy per cent. alcohol. The slide is placed on a horizontal metal plate kept sufficiently warm to soften paraffin. Enough alcohol is poured on to just float the sections. As the paraffin warms the wrinkles disappear. When all the alcohol has evaporated the paraffin may be just melted and then dissolved with benzol or xylol, and finally mounted in balsam. Care must be taken that the metal plate does not get too hot, for if the paraffin melts completely the sections are unsupported. This is a modification of Canini's method, devised by Mr. H. E. Durham.

Gulland's Method.[60]—For serial sectioning, care must be taken that the side of the paraffin block meeting the razor, as well as the opposite edge of the block, is coated with a layer of soft paraffin, and that these edges are parallel with each other.

The ribbons are cut to the proper lengths, floated on warm water (not warm enough to melt the soft paraffin). The ribbons in their proper position are floated upon the slide, which when full is set up on end until the water is thoroughly drained off. The slide is then exposed to a temperature a little below 50° C., where the paraffin of

the sections is not melted, but the water rapidly evaporates. When the evaporation is complete the sections adhere to the slide. The time varies according to the thickness of the section. One hour usually suffices for thin sections. The important point is that the *paraffin must never be melted until the last trace of water has disappeared from the slide.* After complete fixation the paraffin is melted and then washed off with turpentine or xylol.

Gaule's Fixative.[61]—The slide is brushed over with weak alcohol (forty to seventy per cent.); stronger alcohols evaporate too quickly. The sections flatten out on this film, and, if thin, adhere with great pertinacity when the alcohol has evaporated and the slide is perfectly *dry.* "This is no fixative in itself, but simply a means by which the albumin molecules of the section are brought into the same adhesive contact with the glass as those of ordinary fixatives."

Born and Wieger's Fixative.[62]—It is claimed to surpass Giesbrecht's shellac, Mayer's albumin, and Schällibaum's clove-oil and collodion fixatives. It is prepared by adding to every two volumes of quince mucilage (mucilago cydonii) one volume of pure glycerin and a little carbolic acid to prevent fungi. A thin layer of the fixative is spread upon the slide and the paraffin sections placed thereon. No heat is employed; the glycerin prevents the adhesive layer from drying too quickly. Put in a warm place (30° to 40° C.) for twenty minutes or longer. When the water has all evaporated the paraffin is washed out with turpentine, and the slide transferred to absolute alcohol for half an hour at least. Stain with any kind of dye, wash, and proceed as usual. Adhesion remains perfect throughout, and the fixative takes no trace of color; even under the microscope can it scarcely ever be perceived. Two important points in this process are to be remembered: The first is that the slide must be perfectly clean, otherwise the fixative may fail to adhere properly. It is recommended to lay the slides for half an hour in cold soap and water, and dry them carefully with a clean cloth. The second point is, don't transfer the slide from the alcoholic bath directly to water; it should pass at least through one intermediate grade (fifty per cent.), otherwise the diffusion currents are quite likely to separate the section from the slide.

Collodion Imbedding.—Various opinions exist as to the relative merits of collodion and celloidin. The latter is said to be "merely a patent collodion." Lee inclines toward Duval's view, that celloidin has no real advantage over collodion, while the former has the advantage of being more transparent. Apáthy's recommendation, that the celloidin be allowed to dry until it becomes yellow, transparent, and of a horny consistency before dissolving in ether and alcohol, is a great advantage.

After the imbedding of the object in collodion, the collodion may be further hardened, after a short exposure to the air, by immersion in chloroform or alcohol. For general use, except for large objects, chloroform is to be preferred, because it is more certain, rapid, and gives a better consistency to the mass. Alcohols from thirty to ninety per cent. have been recommended for this purpose. The stronger the alcohol, the more likely it is to soften the mass and prevent good results in cutting. From seventy to eighty per cent. alcohols are commonly used, and are to be recommended.

Bumpus's New Method of Using Celloidin for Serial Section Cutting.[63]—"It allows a perfect orientation; the entire object is visible during the process of cutting. Yolk-bearing eggs offer no serious difficulty; sections of large area and of unusual thinness are easily secured; crimping and curling during the process of clearing are avoided, and the sections may be readily arranged in series. After imbedding in a paper tray and hardening in chloroform, and after the paper is removed, the hardened block of collodion containing the object is put into a vial of white oil of thyme, or some other similar oil. The block will become as clear as glass. The specimen is then oriented, and the side of the block to be fixed to the object-holder is wiped dry of the oil and immersed for a moment in ether, and then smeared with thick collodion. The object-holder, a block of wood rather than cork, is smeared in the same way, and the two collodionized surfaces are brought together. The holder and collodion block are now immersed for a few minutes in chloroform, or long enough for them to become firmly united. The preparation is now screwed between the jaws of the object-carrier of the microtome, and covered by means of a camel's-hair brush with oil of thyme. The microtome knife is flooded with the same oil. The oil which thus takes the place of the alcohol commonly used has the advantage, because of its lubricating property, of not only permitting thin sections to be cut, but its slow evaporation allows one to leave his work at any time for minutes, or even hours, without injury to the object. The object satisfactorily oriented, is now cut, and the sections at once transferred to the slides, covered with balsam, and mounted, or, if they are not immediately needed, they may be kept indefinitely in a vial of the oil.

"If the sections are to be arranged 'in series' they are simply placed upon the slide one after the other, care being taken not to flood the slide with oil but to keep it quite dry. After the sections are arranged the slide is tilted up to allow the excess of oil to drain away, fifteen minutes generally being sufficient. Balsam is now placed on the sections, and a warm cover is allowed to fall gently over the series, no section of which ought to leave its place. The above method is especially useful in the preparation of larger yolk-bearing eggs. . . ."

The following method of Eycleshymer's[64] is of great practical utility and abridges considerably the ordinary manipulation of collodion technique. The knife is kept wet with seventy per cent. alcohol. "As fast as cut the sections are drawn back upon the blade of the knife by means of a needle, and arranged in a single row until the blade is filled. To remove them a heavy paper spatula is placed directly upon the section to which it adheres, and may be drawn off the edge of the knife and transferred to the slide. By slight pressure, together with a rolling movement, the section is left in the desired position, sufficient alcohol is kept upon the slide to prevent drying, but not enough to allow the sections to float. When the requisite number have been arranged they are covered with a strip of toilet-paper, which is held on the slide by winding it with a fine thread. [The thread should pass between the sections; if across, the stain is not likely to act there, and a clear disfiguring line will be the result.] The sections being thus firmly held in position may be stained, etc. They should not be placed in absolute alcohol but cleared from ninety-five per cent. in a mixture of equal parts of bergamot-oil, cedar-oil, and carbolic acid. When cleared the excess of fluid is removed by a piece of blotting-paper; with gentle pressure sections which are by chance loose are firmly fixed in position, the thread is now cut, the strip of paper rolled back, balsam and cover applied.

"If the object can be stained *in toto*, which is often the case, much time may be saved by the following method: The stained object is imbedded in the usual manner, but after hardening in chloroform and removing the paper, the celloidin block is transferred to ninety-five per cent. alcohol for twenty-four hours, then to carbolic acid (Bumpus advises white oil of thyme) or glycerine, in which it becomes as transparent as glass (Eycleshymer has since found that the clearing mixture given above answers the same purpose as the carbolic acid but requires a little longer time). The block is fixed in the usual manner.

"Orientation is now accomplished with the greatest ease. In cutting, the knife is wet with the clearing medium given above. The sections may be arranged in serial order on the knife-blade until a slideful is obtained, when they are transferred and balsam and cover applied. By this method long series may be readily handled. Glycerin is used only when the mounting medium is glycerin; in this case the knife is wet with glycerin."

Kultschizky's Celloidin-paraffin Method.[1]—The purpose is to combine the advantages common to each method. After the object is removed from the ether and alcohol

bath it is put into a solution of celloidin of any strength, where it remains for twenty-four hours; it is then transferred to origanum-oil, and then to a mixture of paraffin and origanum-oil, which has been heated to 40° C., and finally to melted paraffin. Its stay in these various solutions varies according to the characteristics of the specimen to be imbedded. The advantages claimed are that very fragile objects can be imbedded; that very thin sections, owing to the celloidin, do not break up, even though the paraffin has given way; that it is not necessary to use an alcoholic drip while cutting; that sections of the same tenuity as those from paraffin imbedding can be obtained.

Ryder[65] modifies the above method by substituting chloroform for the oil of origanum. The sections may be mounted direct from the chloroform (clearing-bath), but the chloroform must not be allowed to evaporate before the section is covered with balsam.

Soap Masses.—These possess many good qualities, they are transparent and very penetrating, and a good mass is said to cut much better than even paraffin. Cutting may be done dry or with alcohol. The mass is alkaline, which is against it for the preservation of tissues, but, according to some, an advantage in clearing up the specimens. It has also been claimed that less shrinkage is produced than with paraffin.

Poli's Glycerin Soap.[16]—A mixture of equal volumes of glycerin and ninety per cent. alcohol are heated in a water-bath to 60° or 70° C. Into this are dropped as many small pieces of glycerin soap as will dissolve. A flask with its neck plugged with cotton, to prevent evaporation, is best adapted to this process. The liquid thus obtained is yellow and transparent, but with a slight opalescence. It is then poured into a capsule or paper box. While it is still warm the object to be cut, and which has been removed from strong alcohol, is fixed in the desired position by means of needles until the soap has solidified. Large pieces must be soaked for some time in a cold saturated solution of soap before they are removed to the warm fluid. The imbedding mixture, which should be kept in a stoppered bottle, melts easily at about 40° C. Very small objects may be imbedded by placing them in a drop of the warm solution on an object-holder and covering them with another drop; with such small quantities the soap gets quite hard in about a quarter of an hour.

The sections are freed from the soap by washing in lukewarm water, while the alkalinity of the soap aids in clearing up the object.

In practice it is found advisable to use two solutions, one for firm and the other for delicate objects. The strong solution is:

Ninety per cent. alcohol	32 c.c.
Pure glycerine	32 c.c.
Soap	64 gms.

The weak solution contains only one-half (32 grammes) as much soap, and is consequently much softer. The mass is said to work very well indeed with delicate botanical objects, and is also recommended for its great transparency and easy solubility in water.

Clearing Agents.—The functions of a "clearer" are to displace alcohol, to render dehydrated preparations transparent and to facilitate the penetration of balsam or any other resinous material in which the specimen is to be mounted. For rendering thick sections transparent a mixture of cedar and clove oil has been recommended.[47] The proportion varies with the quality of the oils. A convenient rule is to begin with two-thirds oil of cedar and one-third oil of cloves, stirring with a flint glass rod. When the rod is no longer visible in the mixture, the correct index of refraction is obtained. A small proportion of Venice turpentine is sometimes added.

Mounting Media.—Under this head will be considered a few forms, chiefly resinous, intended for the permanent preservation of microscopic objects. Canada balsam and damar are in such common use that a mere mention of them is sufficient. Kleinenberg has recommended a solution of *Colophonium* in turpentine. The medium sets slowly but gives good definition.

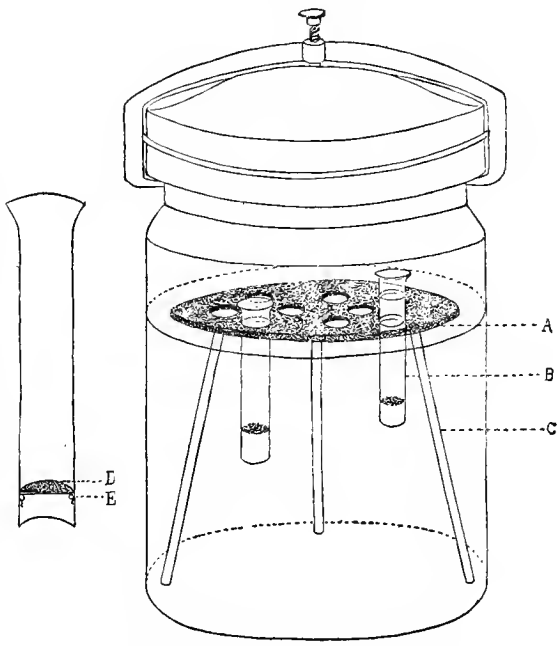
Lavdowsky's Medium.[66]—Two formulæ are given, the first for a thick, and the second for a thin, solution.

Gum sandarac	30 gms.
Absolute alcohol	50 c.c.

For the thin solution dilute this with an equal volume of absolute alcohol. This medium also clears the sections.

Venice Turpentine.[29]—All the advantages and some superiority over the ordinary resinous media are claimed for this preparation. Commercial Venice turpentine is mixed in a tall cylinder glass with ninety-five per cent. alcohol and allowed to stand for three to four weeks and then decanted. A clear yellowish, or sometimes greenish mixture is obtained. And this is at once ready for use. The ordinary solution of Canada balsam is the most suitable consistence for the Venice turpentine. It is stated that most objects can be mounted in this without previous clearing. It sets as closely as damar. Its index of refraction is lower than the above-named balsams, and delicate details are well brought out. Stains are well preserved.*

Cassia-Oil.[67]—This has been recommended as being



Figs. 274 and 275.—Dehydrating Apparatus.

very successful in showing the markings of diatoms. Its refractive index is 1.640.

Levulose (Fruit-sugar).[68]—This substance is found accompanying grape-sugar in fruits and honey. It is uncrystallizable and preserves carmine and aniline stains well (hematoxylin fades somewhat). Objects may be brought into it from glycerin. Its refractive index is somewhat higher than that of glycerin.

Miscellaneous.—*Thomas's Modification of Schulze's Dehydrating Apparatus.*[69]—A disk of plaster of Paris (Fig. 275, A) is supported at a suitable level by glass legs (C) in a museum jar. In the disk are perforations through which the dehydrating tubes are passed (Fig. 275, B). The disk is easily made by pouring a mixture of plaster of Paris and water in a mould of convenient size and depth. The holes for the tubes and the insertion of the legs are attended to while the mass is yet soft. A dehydrating tube (Fig. 274) may be prepared by cut-

* See also a paper by Dr. H. Suchanneck, Zeit. f. Wiss. Mik., vii., 463, 1891.

ting off the bottom of the test-tube, and placing a diaphragm of chamois skin (D) near the bottom. The diaphragm is fastened in its place by means of a spring made of steel wire (E), and forced inside of the chamois skin in the tube, thus pressing the former firmly against the latter. A rubber band around the tubes prevents their falling through the holes, and can be made to regulate the depth to which they shall be lowered into the alcohol. The tissue is placed in the tube containing some weak alcohol, the tube is then lowered until the two liquids are at a level. After twelve or forty-eight hours the two liquids will be of the same strength. The tissue is then taken out and put at once into the infiltrating tube.

With very delicate plant tissue it is well to immerse in as low as five per cent. alcohol in the tube (fifty per cent. suffices for ordinary tissue), or in the case of some algæ even as low as one per cent. The strength of the alcohol in the jar is kept up by adding calcium chloride from time to time. This is said not to injure the alcohol in the least. It is stated that picric, chromic, acetic, or osmic acid can be used with equal success. [It is a question if the presence of the wire supporting the diaphragm of the tube is of any advantage, especially when "acids" are used, and if the same purpose may not be subserved by simply fastening the diaphragm around the end of the tube with a thread.] The advantages claimed are: That not more than twenty-four hours is necessary for dehydrating and hardening nearly all kinds of plant tissue, as no sudden transition from solutions of different strengths occurs the tissue is less liable to shrink. The simplicity of the apparatus places it within the reach of all. Various materials can be used for a diaphragm, and almost any desired speed of dehydrating obtained. According to its size the apparatus may be either for private or general laboratory work. Experiments were not tried with animal tissues, but there is no apparent reason why they should not be successfully dehydrated by this method.

Gage's Drawing-board for the Abbe Camera Lucida.[70]—In order to obtain accurate and undistorted drawings the axial ray from the camera must be at right angles to the drawing surface. To accomplish this the mirror should be tilted to an angle of forty-five degrees. With most microscopes, however, the lateral extension of the stage is so great that a portion of the image falls upon it and renders drawing impossible at this angle. If a lesser angle than forty-five degrees be employed, the axial ray will no longer be at right angles to the drawing surface, although the image may appear clear of the microscope, and an obviously distorted picture will be the result. The board was designed to prevent this difficulty. Upon a board of convenient dimensions is hinged a shorter board (A B), near the attached end of which the microscope is placed (Fig. 276). The drawing surface (A B) may be raised or lowered to any desired angle by simply shifting the wedge (W). The figure with the mirror at thirty-five degrees illustrates clearly the direction of the rays of light, and shows obviously enough the distortion that would result if the board were not used. "*The general rule is to raise the drawing surface twice as many degrees toward the microscope as the mirror is depressed below forty-five degrees.*" A camera with a longer arm attachment would enable the image to fall clear of the stage or base of the microscope with the mirror at forty-five degrees, and a drawing, without distortion, could be made upon the ordinary surface of the table. A quadrant may be easily made and attached by any skilled mechanic.

To Rectify Turpentine for Microscopical Use.[71]—Mr. Charles C. Faris suggests the following method: "Take one-half liter of the common turpentine and mix in a liter bottle with one hundred and twenty cubic centimetres of ninety-eight per cent. alcohol. Agitate well, and let stand until the two fluids separate. Decant the turpentine (which will form the lower layer) from the alcohol and mix it with one-half liter of clear water. Agitate thoroughly, and let stand until these two fluids separate; then from the water decant the turpentine (which this time will form the upper layer), and finally mix with the turpentine about thirty grams of powdered starch and filter through paper.

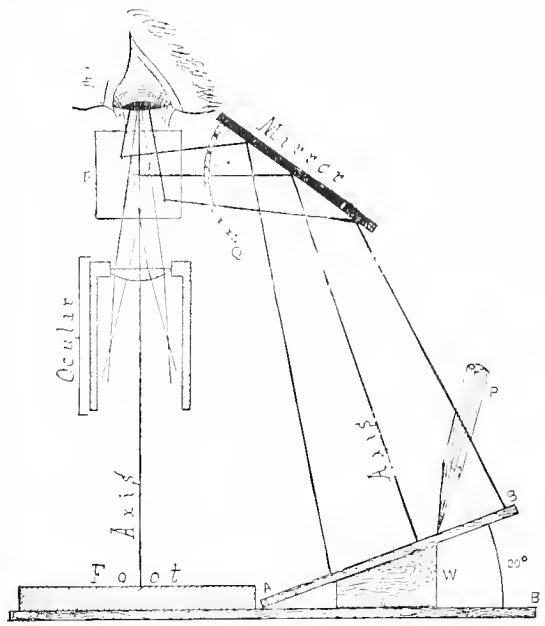


Fig. 276.—Drawing-board for Microscope.

"By pursuing the foregoing plan any one may secure a pure, limpid, and brilliant turpentine. The alcohol used in rectifying it need not be wasted, as it will do to burn, to clean slides, or for other purposes. I usually make a large quantity and recover the alcohol by distillation."

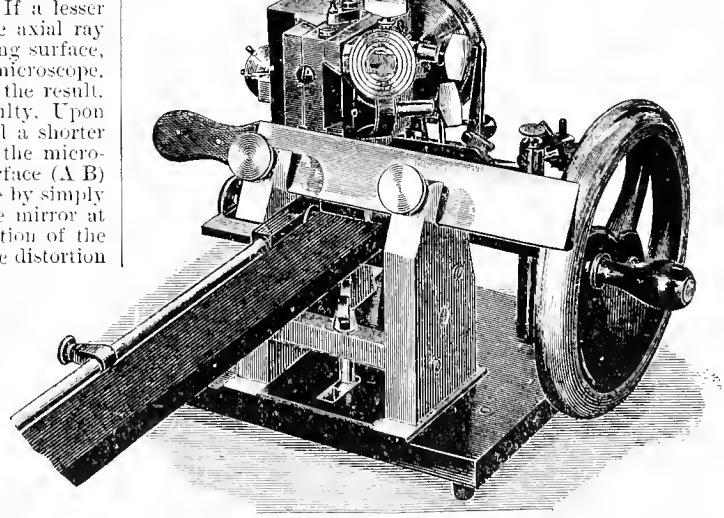

Fig. 277.—Minot's Improved Microtome. Front view.

Microtomes.—The following brief description is confined entirely to instruments of American design, although Figs. 277 and 278—the front and rear views of Minot's microtome[72]—show some modifications very recently introduced by a foreigner (Zimmerman). The principle of the microtome is to secure sections by

moving the object to be cut in a vertical plane past the knife, which is held in a fixed position. The slide A (Fig. 277) moves up and down. In this figure it is represented at its highest level above the knife. To this (the vertical) slide is attached another, the horizontal slide, which is moved by a micrometer screw, the head of which is a cogged wheel, B. In the knife end of this slide is clamped the object-holder. This may be turned until the object is in the desired position and then fastened by screws. From a movable bar attached to the vertical slide is a hooked lever, which catches in the teeth of the large wheel B.

The free end of the bar projects far enough beyond the hooked lever to strike against one of the six arms of a windlass arrangement at the side; this causes the lever hooked in the wheel to be pulled down, thereby turning the wheel and moving the horizontal slide with its object-carrier toward the knife. The arms of the windlass are of different lengths, and the distance through which the horizontal slide moves is proportionately greater or less, thus regulating the thickness of the sections. These can be made to vary from three to twenty *microns*.

For thinner sections the small wheel C (Fig. 278) is adjusted so that its cogs will fit into those of the large wheel B, the windlass of which is not now used, but in place of it one regulating the turning of the small wheel C. With this arrangement sections can be made from one to six *microns* in thickness.

Fig. 277 shows a belt attachment fastened to the knife supports, for the purpose of enabling the worker to more easily manipulate his "ribbons" of sections. By simply turning the wheel, section after section can be cut with the greatest rapidity.

Compressed Carbonic Acid Gas for the Freezing Microtome.[73] — The gas, or liquid carbonate, as commonly known, is obtainable in ten- or twenty-pound cylinders. For laboratory use certain changes must be made in the cylinder. "A circular block of iron, an inch in thickness and of the diameter of the handle of the valve, was fastened to the latter by two screws with nuts. Into this block were bored four holes ninety degrees apart, and of a size sufficient to admit the end of an eight-inch handle, B (Fig. 279). This greater leverage affords much better and more even control over the escape of the gas.

"The cap covering the escape-pipe was unscrewed, and a hole bored through it large enough to admit of a small brass tube with a fine bore being driven tightly into it. The cap thus prepared can be kept and used on any other cylinder received. One end of a small but thick rubber tube, C, was then slipped over the brass tube and tied firmly on; the other end was fitted over the tube leading into the freezing-chamber of the microtome, but was not tied on, so that it might act as a safety-valve and slip off if the pressure became too great; otherwise the tube is likely to inflate and explode. In connecting the cylinder with the freezing microtome it must be inverted, so that the valve handle is below, and raised enough above the table to bring the escape-pipe on a level with the freezing-chamber. A projecting support at A and two bands

Fig. 279.—Carbonic Acid Gas Cylinder, for Freezing Microtome.

at D, sufficiently snug to keep the cylinder from turning, were found necessary. The freezing chamber of the microtome should be shallow (about five millimetres) so that the gas, which by its own evaporation becomes frozen solid in it, may continue to free the specimen above it. The brass plate above the chamber should be thin, but still strong enough to stand considerable pressure, and the floor of the chamber ought to be made of a block of solid hard rubber, in order to render the loss of cold as small as possible." (F. B. Mallory.) This method is much cheaper than that by ether or rhigolene. If a specimen is frozen too hard, so that it chips, simply passing the finger wet with water or salt solution over its surface, will soften it. A carpenter's plane properly mounted makes the best knife for cutting.

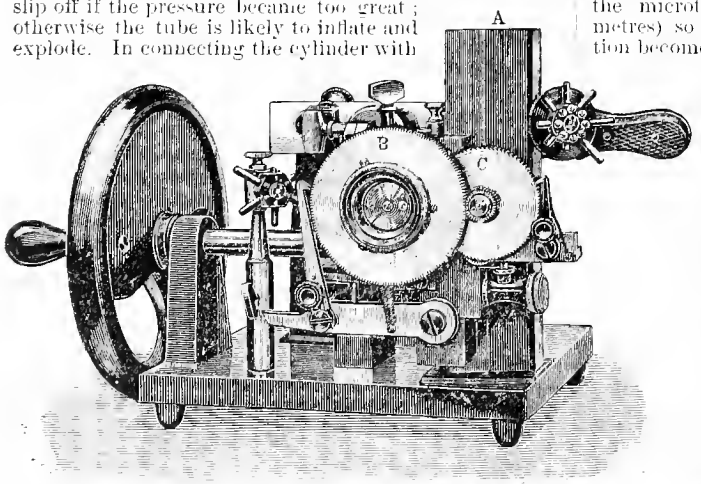

Fig. 278.—Minot's Improved Microtome. Rear view.

Ryder's Automatic Microtome.[74] — "The working parts are an oscillating lever, which is provided with a clamp at one end into which the paraffin-holders are adjusted, and at the other with a simple handle. This lever rests upon trunnions on either side, and these in turn rest in triangular notches at the top of the two pillars between which the lever oscillates. At the cutting end of the

lever a spring pulls the lever down and effects the sectioning and also the adjustment for the next section. The lever is pushed over and adjusted for the successive sections by a hollow screw, through which passes the trunnion on the side away from the knife. This screw is fixed to a toothed wheel, three inches in diameter, which revolves close by the side of the oscillating lever. The toothed wheel and screw are actuated by a pawl fixed to the side of the lever near the handle. The number of teeth which this pawl can pass in a single vibration downward is controlled by a fixed stop screwed into the under side of the oscillating lever near the handle; the end of this stop striking on the top of the bed-plate thus brings the lever to rest at a constant point in its downward excursion. An adjustable sector by the side of the toothed wheel throws the pawl out of gear after a given radius of the wheel has been turned through an arc embracing the desired number of teeth. This adjustment is also effected before the block containing the object to be cut reaches the knife. The adjustment for the next section is therefore effected while the surface of the block is not in contact with the under side of the knife, so that no flattening or scraping effect is produced on the surface of the block in its upward passage past the knife.

"The movement of the vibrating lever being arrested at each down-stroke at one point, and the pawl

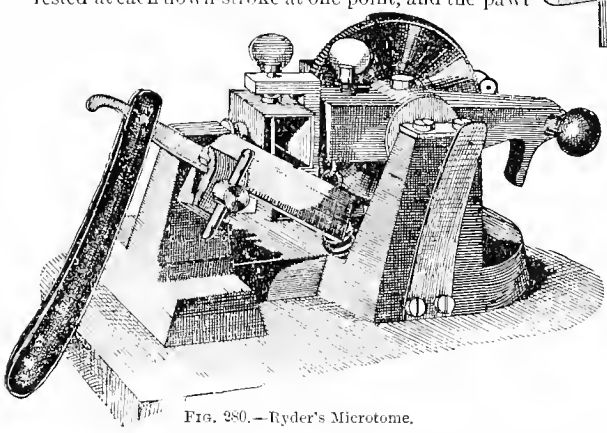

Fig. 280.—Ryder's Microtome.

which catches into the notches in the toothed wheel being released at any desired point by the action of the adjustable sector, it is possible to adjust the apparatus with great accuracy for cutting sections of any desired thickness. If a given radius of the wheel is moved through the arc embraced by a single tooth, sections are cut having a thickness of only two and a half *microns*, a thickness which is only practically possible with paraffin imbedding and a very keen razor. If more teeth are taken by the pawl, any thickness of section is possible up to about sixty-two and a half *microns*.

"A freezing attachment which has lately been appended to the apparatus shows that frozen sections can be made with as great rapidity and success as those cut from objects imbedded in the paraffin block, and very nearly, if not quite, as thin. The freezing attachment is as simple and efficient as the self-adjusting and cutting devices of the instrument. Other auxiliary apparatus makes it possible to cut celloidin sections. This is effected by means of alcohol, conducted by a tube from a reservoir to the knife, over which the fluid will run and drain into a tray below in such a way as not to come in contact with any other part of the machine. This tray fits into a recess in the side of the bed-plate of the instrument, just below the knife, and into this tray the celloidin sections may be allowed to drop as fast as cut. The knife can be placed at any desired angle, which, for some kinds of work, is quite a desideratum."

King's Microtome.—A microtome designed especially for hard service in botanical work or for cutting any hard material which requires absolute rigidity in the instrument. The knife is attached to a heavy nickel-plated iron carriage *A* (Fig. 281) by a steel clamp and shoe, *b* and *c*, with milled-head screws, *a*. The carriage runs on a solid iron track, *h* and *B*, which is held to a table by clamp screw, *k*.

For cutting very hard objects, like the wiry stems of plants, or the chitinous skeletons of insects, there is an attachment with a very stout blade, on the principle of a carpenter's plane, *d*, which screws on to the carriage in place of the knife, and like it can be used for transverse or oblique cutting. Two forms are made; No. 1 will cut paraffin objects to two and a half *microns* in thickness; No. 2, only to twelve and a half *microns*.

An Inexpensive Section-smoother.[61]—A very simple device. It is prepared by cutting off the head and point of an ordinary pin and fixing it parallel to the edge of the knife by pressing its ends into two small pellets of beeswax. (Fig. 282.) The proper elevation can be determined by experimenting on waste paraffin before the object is reached. The pin is used only for transverse cutting.

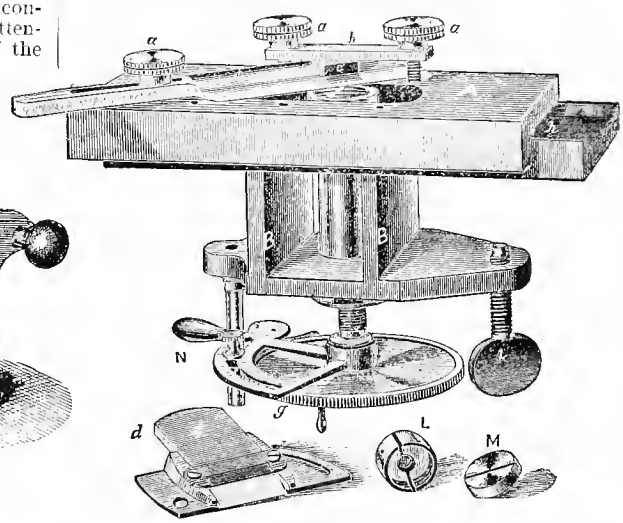

Fig. 281.

Decolorizing Preparations Over-blackened by Osmic Acid.[45]—Dr. E. Overton reminds histologists of a method introduced by Fol. The solution is not permanent and should be prepared afresh whenever needed.

Commercial peroxide of hydrogen. . .	1 part.
Alcohol (seventy to eighty per cent.).	10–25 parts.

The treatment lasts but a few minutes, after which the preparations stain excellently.

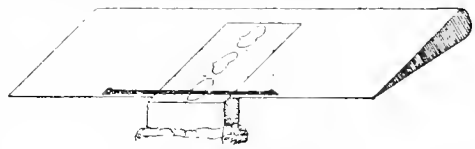

Fig. 282.—Section smoother.

Schieffердecker's Microscope Screen.[72]—The general form and relative size are well shown in the figure (Fig. 283). The framework is made of light wire, around which is sewed some dark cloth. At the lower part, and forming a support to the screen, is a metal rectangle; from this there extends upward a vertical strip which a little above the level of the coarse adjustment is bent at right angles to join two pairs of arms embracing the tube of the microscope. The base of the rectangle rests upon the front of the stage. By moving the tube of the microscope the whole screen is moved up or down. From the lower edge of the rectangle there hangs down a small piece of cloth to screen the condenser, while the main portion

amply protects the eyes and the object under examination. With a little ingenuity less elaborate but equally efficient screens may be made; their usefulness is well worth the time expended.

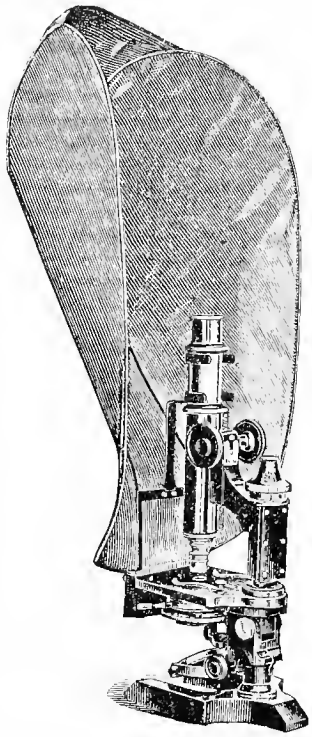

Fig. 283.—Screen for Microscope. (Schiefferdecker.)

The Removal of Aniline Dyes from the Hands.[76] — Some dyes resist very stubbornly the action of alcohol or hydrochloric acid, and require some bleaching agent. Unna recommends washing first in a solution containing a little common salt (about five per cent.), and then in a solution of hydrogen peroxide of about the same strength, and finally wiping with a cloth moistened with alcohol.

Ward's Eye Shade.[70] — This device consists of a black disk, from which extends an arm curved at its end and somewhat elastic, in order to clasp the ocular. By its use both eyes may be kept open, thus avoiding fatigue.

Fig. 284.—Eye Shade. (Ward.)

Blum's Regeneration of Hematoxylin.[72] —As hematoxylin is rather expensive, a method for restoring it may be worth knowing. To about 200 c.c. of the used hematoxylin, add from five to ten c.c. of baryta water (an aqueous solution of barium hydrate). A stream of carbon dioxide, made from marble and hydrochloric acid, is then passed through it, and after twenty-four hours it is filtered. The filtered solution is said to be as good as the original.

The Restoration of Osmic Acid Solutions.[77]—Osmium tetroxide, OsO_4, is readily reduced in the presence of organic matter, giving up two atoms of oxygen and forming the deutoxide, OsO_2. The tetroxide affects fatty substances first, and these are the substances that most readily undergo oxidation. After some preliminary experiments with peroxide of hydrogen, (H_2O_2), with uniformly good results, it was found that the restored solutions, with the exception of a gradual weakening, acted in the same manner as the fresh solutions and produced the same results.

The chemistry of the restoration and the bleaching further demonstrate that no injurious factor enters into the result, as is shown by the following equations:

OsO_4 + organic substance = OsO_2 + oxidized organic substances.

$OsO_2 + 2H_2O_2 = OsO_4 + 2H_2O$.

That is, in bleaching a tissue its OsO_2 is converted into OsO_4 and water is formed.

To restore 100 c.c. of a one per cent. solution of osmium tetroxide requires from ten to twenty drops of fresh peroxide of hydrogen, and clearing goes on better in full sunlight. To bleach tissue with peroxide requires about the same amount in 100 c.c. of water, and the bleaching takes place in the sunlight also. The amount needed cannot be stated with any more precision, because the peroxide loses its strength somewhat with age.

Reconstruction Points.[63]—An ordinary metallic imbedding box, Fig. 285, made of two L-shaped pieces, *a* and

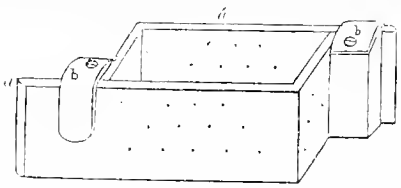

Fig. 285.—Imbedding Box.

a', held in place by the overlapping strips *b*, is perforated at the ends and sides, in as many places as are desired, by a very small drill. These should be so arranged that the silk threads when drawn through are parallel. The threads are cemented to the sides of the box with five or six centimetres left hanging. A heavy piece of blotting-paper is fitted in for a bottom. The object is placed upon the threads in the desired position and the imbedding mass poured in. When hardened the celloidin holding the thread is dissolved with ether. The loose ends are soaked in a weak solution of celloidin to which has been added some lamp-black. The threads are then drawn through, leaving the lampblack adhering to the celloidin, thereby forming excellent reconstruction points.

For small objects, where reconstruction points are not needed, Mr. Eycleshymer recommends the following method: The heads are clipped from fine insect pins, which are then placed in handles in such a way that they may be easily removed. On these pins the objects are oriented in the desired position; the pins are then removed from the handles and fixed in a cork, *a* (Fig. 286), previously perforated by a somewhat larger pin. As fast as the pins carrying the objects are inserted, the cork is replaced in the tube, which is filled with alcohol. A half-dozen fish or amphibian ova may be oriented on the same cork. If desirable to draw the objects *in situ* a piece of lead may be pinned to the cork and the whole immersed in a small beaker of alcohol. The corks carrying the oriented objects are transferred successively to tubes containing the different solutions. When ready for final imbedding, a piece of porous paper is wrapped about the tubes and cork, and pinned. The cork is now removed, allowing the imbedding solution to fill the paper tube thus formed. A lead is fastened to the cork and the whole placed in chloroform until hardened, after which the paper is cut from the mass and the pins drawn through the cork, when it is ready for sectioning. Several objects may be cut at the same time, drawings may be made after

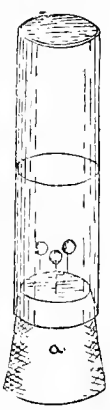

Fig. 286.—Vial for Orienting Small Objects.

orientation, and the objects may be transferred more rapidly from one solution to another.

A Breath Screen.[29]—In order to avoid the accumulation of moisture along the tube of the microscope, especially in winter, Dr. P. Schiemenz has devised the screen shown in Fig. 287.

It is made of a piece of stiff paper, the principal part of which is nearly circular (diameter, about 8 ctm.). The

Fig. 287.—A Breath Screen. (Schiemenz.)

smaller portion is pierced by two holes, through which passes a string by which the apparatus is attached to the microscope tube. The screen is easily fixed and moved to any desired position.

Accurate Drawings by Amateurs.[60]—A blue print, not too dark, is traced over free-hand, with China ink. When dry the picture is passed through an aqueous solution of caustic potash, 1 in 500 or 1,000, and washed afterward with water and dried. The potash removes the blue printing, leaving the ink lines distinct. If the print is too dark, delicate outlines are not easily seen and the bleaching process is not so thorough, a brownish tint remaining.

The drying is an important part of the process. As soon as washed the picture should be placed between some sheets of blotting-paper, and dried quickly by rubbing the hands over it a few times. If this precaution is not taken, the ink particles are likely to run, giving blurred and indistinct lines. "In this way drawings, with all the accuracy of photographs, and all the clearness of woodcuts or etchings, may be produced by persons who cannot make anything like an accurate drawing or a good picture of any natural object. There is a minimum of trouble and expense."

A Waterproof Drawing Ink:[76]

Powdered bleached shellac	4 parts.
Borax	1 part.
Water	24 parts.

Dissolve by the aid of heat. To this solution the coloring principle, as India ink, lampblack, the different tints and shades of anilin colors, etc., is added after being dissolved in, or triturated with, a small quantity of water.

An Inexpensive Reagent Block.[59]—"It is a plain white-wood block, 15 ctm. square and 4 ctm. thick. On the upper side of this three grooves are cut, each 1.5 ctm. deep. The first is 1 ctm. from the edge, and 1 ctm. wide; the second is 1 ctm. from it and 3.5 ctm. wide. The third is 1 ctm. from this and 2 ctm. wide. Into one end there is glued a closely-fitting block, 1 ctm. long, and in the other end one 5 ctm. long, leaving a trough for slides about 9 ctm. long. In the place where this last block is glued, is bored a hole 1.5 ctm. in diameter, and 1 ctm. deep, into which tightly fits a paper pill-box for covers. The remainder of the block is provided with two rows of five holes, each 2 ctm. in diameter, and 3.5 ctm. deep, for reagent vials.

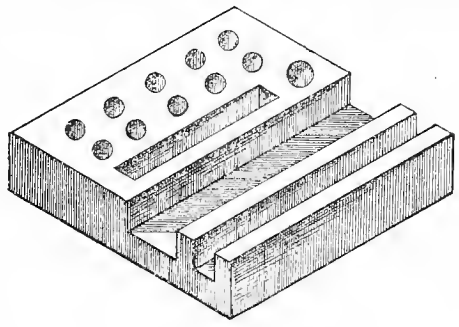

Fig. 288.—Reagent Block.

The first groove is used for razor and the second for pencils, pipette, forceps, etc. The block is easily made, costs very little, is very neat in appearance and convenient in work."

Bausch and Lomb's Cover-glass Gauge.—The stand is made of japanned iron; at the top, cut horizontally, is a thread $\frac{1}{50}$ inch pitch and $\frac{3}{16}$ inch outside diameter. A recess is cut below the line of the screw and at a right angle to it, for placing the covers. The portion of the stand at the side of the recess which receives the micrometer screw, is slotted longitudinally to the depth of the screw, and is provided with a set screw to take up wear; the other side has the "fixed" screw, which is, however, adjustable. The end of the micrometer screw is milled so that no force can be exerted sufficient to endanger the cover-glass. Fixed to the screw is a wheel, the surface of which is one-half inch wide. A knife-edge index-finger attached to the top of the stand pro-

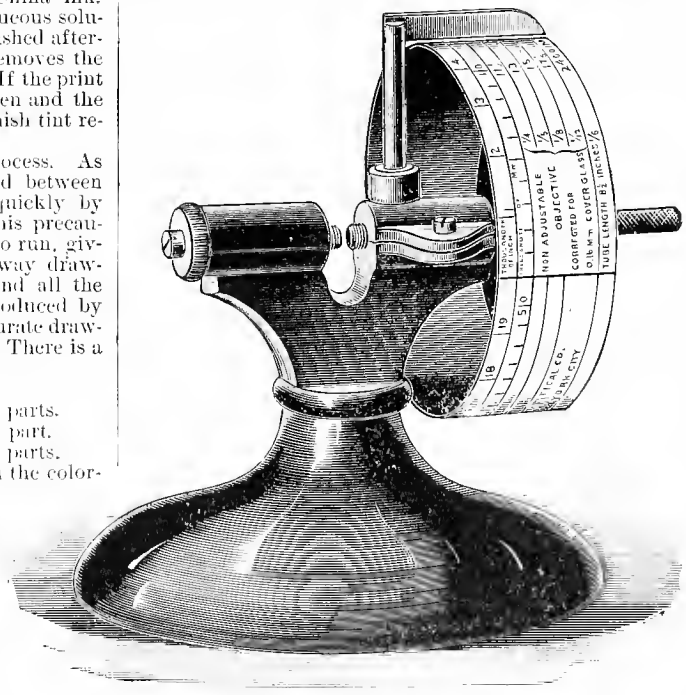

Fig. 289.—Gauge for Cover-glasses.

jects over it. Along the circumference of the wheel is fixed a strip of glazed paper provided with a series of divisions. The first series gives the thickness of cover-glasses to one-thousandth inch, the second to one-hundredth millimetre, and the third indicates the proper tube-length with various thickness of cover-glass, with a non-adjustable ¼-inch objective corrected under a tube-length of 8½ inches and cover thickness of 0.16 mm.;

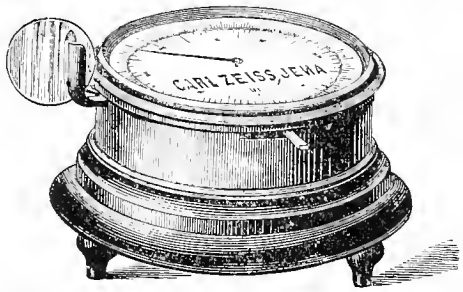

FIG. 290.—Zeiss's apparatus for Measuring the Thickness of Cover-glasses.

the fourth gives the tube-length of a ½-inch objective under the same conditions; the fifth for a ¾, and the sixth for a $\frac{1}{12}$; the seventh is for a ⅙-inch objective with the same cover and tube-length of 160.0 mm.

Zeiss's Cover-glass Tester.—For determining the thickness of cover-glasses, etc. A small lever projecting from the side of the apparatus regulates the opening and shutting of the jaws for holding the cover-glass. An indicator moving around a circular scale on the face of the box, registers the thickness of the object. The divisions of the scale show hundredths of a millimetre and thousandths of an inch.

Micrometer Caliper.—Used chiefly in the "mechanic arts." It is, however, perfectly well adapted for testing the thickness of cover-glass. It can be obtained with either the English or metric scale, and is of convenient size so that it may be carried in the vest-pocket.

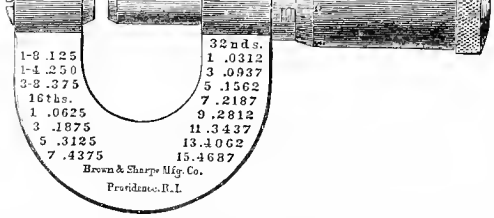

FIG. 291.—Micrometer Caliper.

Cleaning Mixture for Glass.[70]—Various formulæ have been given for cleaning new and used slides and cover-glasses. The following have been well-tested and deserve high recommendation:

Bichromate of potash	200 gms.
Water	1,000 c.c.
Sulphuric acid	1,000 c.c.

Dissolve the bichromate in the water by the aid of heat, pour into a bottle wrapped with a wet cloth, and add the sulphuric acid slowly and at intervals. The mixture may be used more than once, but when markedly of a greenish tinge it should be discarded. Another good mixture is:

Nitric acid	200 c.c.
Sulphuric acid	300 c.c.

The two acids should be mixed slowly and, like the preceding, kept in a glass-stoppered bottle. It is a more rapidly acting mixture, but the fumes render it less desirable.

Waste Bowl.—The apparatus is easily constructed and exceedingly useful. The ends of two glass rods of the proper length are fastened into two strips of lead, slightly curved to fit around the margin of an ordinary bowl. Between the glass rods is a tin funnel, held in position by flanges of tin which may be bent around the rods and permit the funnel to slide back and forth. The rods are a convenient resting-place for the slide, while in

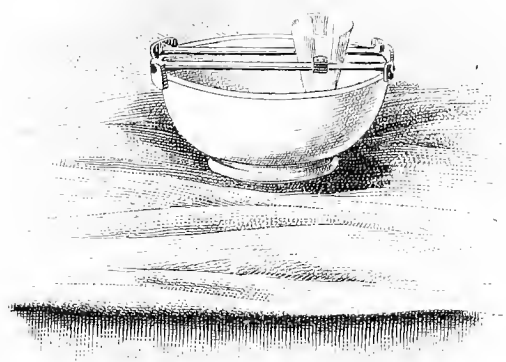

FIG. 292.—Waste Bowl.

process of preparation. The various solutions used in treating the sections may be readily drained from the slide by placing it for a few moments in the funnel.

Pierre A. Fish.

BIBLIOGRAPHY.

In compiling these formulæ it has been the aim of the writer to consult the original papers. It has been impossible in some cases, with the limited time at his disposal, to do more than to secure abstracts of them in other periodicals; but it was deemed better, on the whole, to give the reference directly to the complete article.

HONFLEUR. A seaside resort facing Havre, on the other side of the river Seine. Although the place is decidedly popular and even fashionable, the beach is muddy and bathing is not of the best. The sea-air is, however, bracing, and many English have selected Honfleur as a place of residence. The hotels are fairly good, the principal one being the *Cheval Blanc*, situated on the quay. There are good opportunities for excursions, both by land and on the sea. The town itself is not especially attractive. *Edmund C. Wendt.*

HOSPITALS, CONSTRUCTION AND MANAGEMENT OF. The history of hospital construction during the last decade is especially interesting in some of its particulars. There has been ample evidence of advancement in the application of the principles that were largely evolved from the experiences of the civilized world in the care of the sick and wounded of the great wars in the third quarter of the century. There is now not only a more general understanding of the way to build good hospitals, but other influences have been at work, making it comparatively easy to build, administer, and support them.

The science of hospital construction has been taking a more definite form, as is shown by the literature of the subject, which has received some notable additions since the publication of the valuable work of Mouat and Snell, ten years ago. The description of the Johns Hopkins Hospital, in a quarto volume, with its plans admirably complete in the detail they give, is an instructive source of information for all builders of hospitals. The recent publication of Burdett's great work on the "Hospitals and Asylums of the World," with its four volumes and portfolio of plans, is the most excellent presentation of the subject, in all its departments, that the world has yet seen.

A distinctly new phase of hospital work has reached a fuller development than ever before. It is the more general distribution of small hospitals in the smaller cities and towns. The tendency in this direction, though long existing, has been slow in its results until the rapid progress of the last few years. It is not many years since there were few hospitals for general medicine and surgery outside of the large cities. The great hospitals, while being local charities for the treatment of the more ordinary ills, were almost the sole seats of hospital work and its medical and surgical clinics, with their notable cases, and capital operations by notable men. But there was bad hospital construction, with its evil consequences, and the lack of modern skilled nursing, that now makes it possible to do good work even in some bad hospitals. The physician in private practice, at that early day, had conditions often better than those of the hospitals for the splendid work that was done by individual men under circumstances in many ways adverse to success. Almost any healthy house gave the sick man a better chance than the hospitals, except for the pre-eminent skill derived from the experience gained in them.

The great change that has come about in hospitals and their work, particularly in that of surgery, was first largely due to the use of anæsthetics. After that the world learned how to make hospitals healthy, and the skilled nurse came to multiply the resources of the physician and surgeon. But while the mechanism of hospital work was becoming more complex, it became more precise. Successful surgery, for example, formerly demanded certain qualities of boldness, swiftness, and the like, as well as scientific knowledge. There were fewer surgeons then than now. Modern progress has tended to the development of specialties, particularly in those involving surgical manipulations. These are now applied with more deliberate judgment, and more of the precision of an exact science. With the safeguards of asepsis, conservative surgery, and medicine as well, have made possible some of the greatest scientific advances. The modern surgeon may achieve success through study, time, and practice of very definite methods. Boldness and swiftness are largely supplanted, or tempered, by caution and painstaking attention to details. These are still consistent with the courage that is based upon better knowledge. With more complexity of manipulation in the art, special conditions for its practice have become more necessary. The increasing wealth of the country and its growing philanthropy, are in happy union with the greater need of hospitals, which has come because so many things can be done only in them, or so much better done than in private homes. The appreciation of this has led to the establishment of many small hospitals within a few years. They are aided in their support by the custom that requires patients to pay according to their means. In New England especially many of the smaller towns have their hospitals, or are beginning to get them. They have become possible also, as to their successful management, through the services of trained women.

We are witnessing, in one generation in civilized countries, both a great change in social life in some of the particulars here referred to, and the evolution of preventive and conservative medicine in ways that were never possible before. The skilled nursing that was at first taught only in the schools of the great hospitals, was elsewhere chiefly the luxury of the rich. It is now getting nearer to the poor in their homes, and becoming the boon of the greater public that has heretofore been so much beyond the reach of the common hospital privileges of the large cities. It is not meant to say that these conditions are peculiar to New England, but in the eastern section of it they have reached a further development than elsewhere in this country. Within less than a dozen years a number of small hospitals have been built in that section, and it does not need a prophet to predict the coming of the time when there will be the "cottage" in every town adapted to hospital uses for its locality, and supported in part by public money. They will be the common schools of nursing for the local service.

While there has been an extension of hospital construction, on the lines of the correct principles now so well established in these small hospitals, a departure has been made from previous ideas in the invention of special constructional devices for promoting aseptic surgery. A few unique examples of such surgical buildings are now in existence.

The great advances in bacteriology have also stimulated much attention to infectious diseases, and the building of special hospitals for their isolation and treatment is becoming more common. This affords another example of the progress of preventive medicine, and the village hospital should become a part of the general system of preventive care of infectious diseases.

The purpose of this article is to note recent progress in hospital construction in the three ways that have been mentioned. The first of these relates to the extension of the English cottage hospital system in America in recent years. In some cases dwelling-houses have been inexpensively adapted to the purpose; and slow progress was made, at first, because the cost of specially constructed buildings was beyond the available means. But while it has been sought to get what is wanted at a moderate cost, the value of the thing itself has become better appreciated. The ways of raising money for such purposes have been learned, and there is more liberal giving. Still the demand is for small effective hospitals at such an expense that every thriving community in the country can make available for the common need the proper conditions for modern medical and surgical treatment.

The City Hospital of Quincy, Mass., is an excellent example of what has been done in providing a hospital that, in the three years of its existence, has made a creditable record, and become a model of construction that others have followed. The hospital, with the administration house and one of its two wings, cost when completed for use $16,500, and with three and one-quarter acres of land, valued at $8,000, was given to the city by Mr. W. B. Rice. The furnishing cost about $3,000, and, with almost all the equipment, was paid for by societies and individuals; the hospital on completion was free from debt. The endowment fund for free beds reached the amount of $33,600 in the second year. The support of the hospital is aided by the city, by receipts from private patients, and by collections from various sources. A "Hospital Aid Association" also makes valuable contributions from its membership of seven hundred, at an annual fee of one dollar each, besides rendering aid in other ways.

The hospital has a capacity of twenty-five beds; it was opened in June, 1890, and admitted one hundred and two patients the first year, and one hundred and forty-six the second year. The net cost of support is something over $8,000 per year.

The building, designed by W. P. Wentworth, the architect, is of wood, and occupies a fine, elevated site with a southerly aspect. The plan (Fig. 293) shows two one-story pavilions, one of which is not yet built. The pavilion contains fourteen beds; there are six rooms for private patients and a small ward in the second floor of the administration house. The heating is by steam, by indirect radiation; there are ventilating openings under the beds leading to a vent shaft two feet square, and others in the ceilings are connected with ventilators in the roof; there are also fireplaces in the wards and rooms. All rooms have rounded corners in the plastering; the hard-pine floors, and white-wood finish, also have all angles rounded. The plumbing is modern with all pipes, etc., exposed, and the drainage is good.

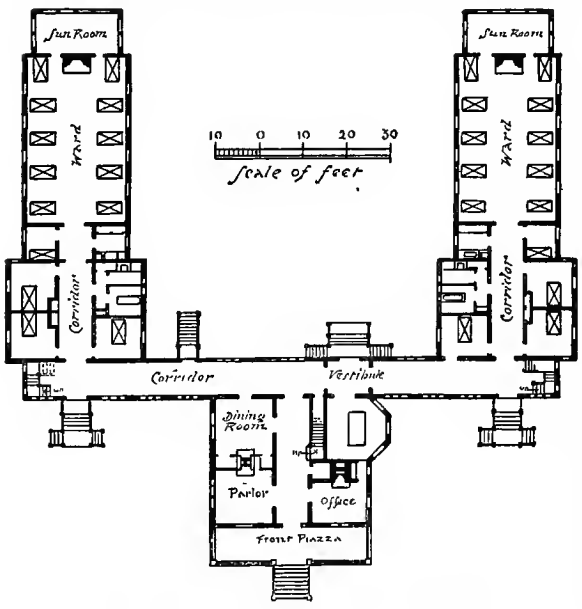

Fig. 293.—City Hospital of Quincy, Mass. First Floor Plan.

The hospital is under the charge of a matron, who is required to be "an educated and skilful nurse." There

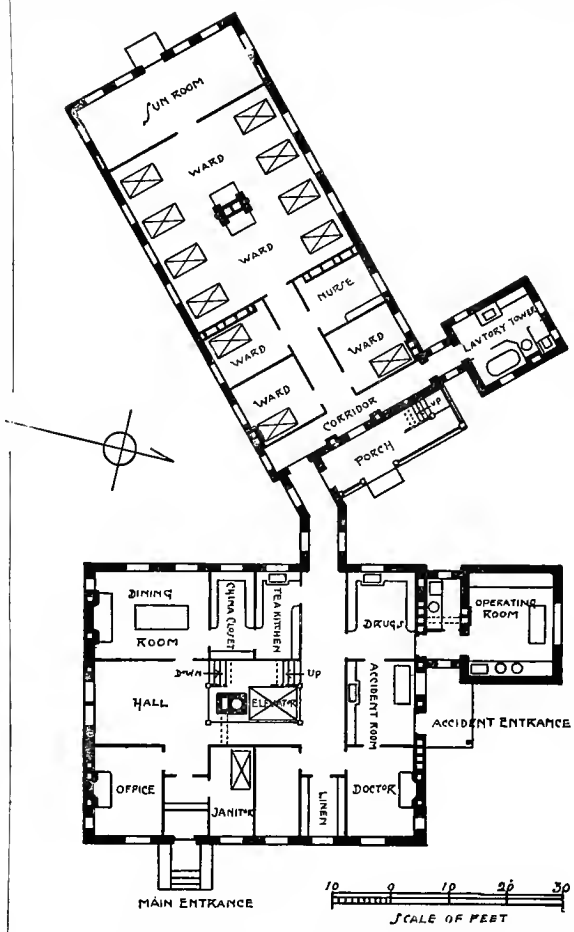

Fig. 294.—The Waltham Hospital. First Floor Plan.

is a regularly organized training-school, and some income is derived from the employment of pupil nurses outside of the hospital. A corporation of over three hundred members elects twelve trustees, who control the management of the hospital through an executive committee. There is a medical board that nominates the members of the medical and surgical staff, which includes physicians of both regular and homœopathic schools. The details of organization and management here given afford a good example of the method adopted in many of the small hospitals.

A new hospital at Waltham, Mass., opened within the past year, is built upon a plan in which the "mill principle" is applied for the first time in such a structure, "thereby securing numerous advantages at a comparatively small cost." The architect was William Atkinson. There are two plain, rectangular, substantial buildings of brick. The administration house, three stories high, contains the offices on the first floor, six private rooms on the second, and the kitchen and laundry on the third floor. A two-story pavilion contains on each floor a ward of eight beds, and one bed in each

of three separate rooms. The capacity of the hospital is twenty-eight beds, and Fig. 294 shows the general arrangement of the buildings. Their oblique position is due to the peculiar conformation of the lot upon which the hospital stands. The outside walls diminish four

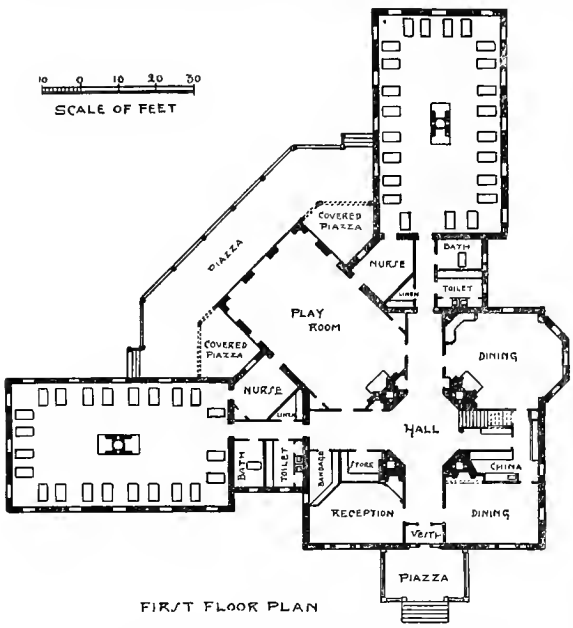

Fig. 295.—Convalescent Home for Children, Wellesley, Mass.

inches in thickness at each story. The peculiarity of construction is that the floors and roof are of plank, laid on hard-pine timbers; and the interior partitions are of three-inch spruce plank, grooved and splined and set up vertically. The walls and ceilings of the ward building are finished throughout in adamant plaster, as are also the six pay-wards for single beds, and the accident and operating-rooms of the main building. For the rest of the building, the brick walls and the plank partitions are finished in varnish. The object gained in this method of construction is that it is economical and "slow-burning," it being possible to have no concealed spaces in the walls or elsewhere. The heating is by steam, and the distribution of the warm air is aided by a propulsion fan. The inlets are seven feet above the floor, and the ventilating outlets are at the floor level; all the flues are built into the brick walls. The cost of the completed building, including plumbing and heating apparatus, was about thirty-eight thousand dollars.

There is an endowment fund for free beds, and substantial contributions to the support of the hospital are received through the work of the "Ladies' Hospital Aid Society." The executive officer of the hospital is a matron, who is a trained nurse. The nursing service is entrusted to the Waltham Training-school for Nurses, which is a peculiar institution; it was a successful organization before there was any hospital, and the training was given entirely in the work of "home nursing." The novel plan of this school and its foundation are due to Dr. Alfred Worcester; it is worthy of careful study and imitation, for it makes possible the advantages of trained and skilful nursing in places where hospitals cannot be afforded. It provides also a way for the helpful enlargement of the facilities for instruction in the small hospitals. The trustees are preparing for the reception of infectious and contagious cases, a disinfecting station, and an ambulance service.

An interesting variation of a one-story pavilion plan for a general hospital is given in Fig. 295, showing the arrangement of wards and rooms in the Convalescent Home, at Wellesley, connected with the Children's Hospital in Boston.

The building is of brick; it is beautifully situated in grounds that have liberal space and shade; and it is admirably adapted to its special purpose. It is so situated that the windows opening upon the piazza look to the south. The administration building is of three stories; and each of the pavilion wards contains twenty-three beds. The cost of the completed hospital approximated fifty thousand dollars.

A fine example of the double pavilion plan of construction has just been completed at Hanover, N. H., in the neighborhood of Dartmouth College. The Mary

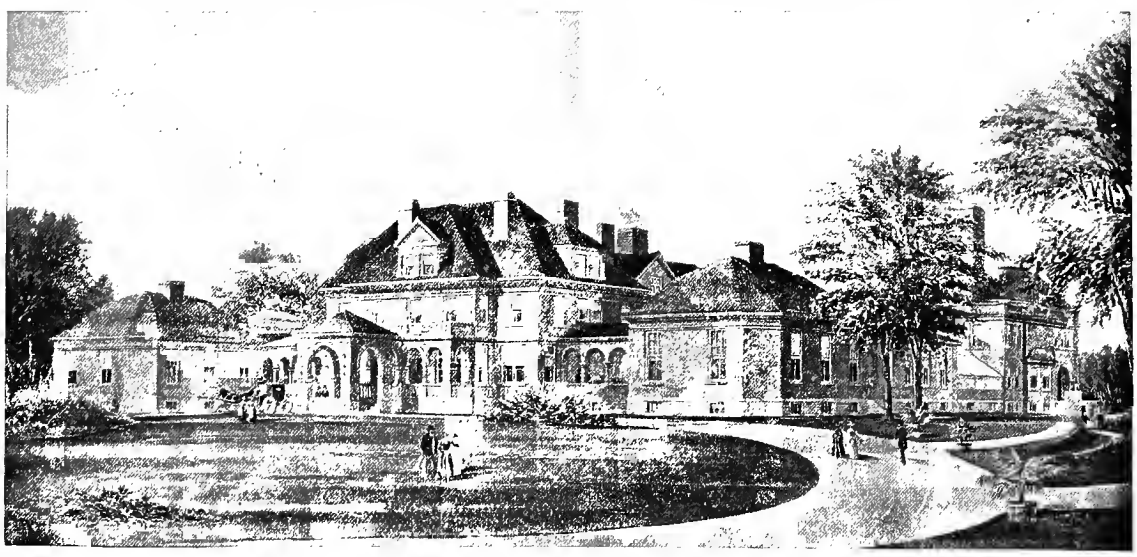

Fig. 296.—Mary Hitchcock Memorial Hospital.

Hitchcock Memorial Hospital is the generous gift of Mr. Hiram Hitchcock, of New York: its benefits will be felt by the College, Medical School, and the town and country around. The perfection of the building is due to the aim of the donor to provide everything desirable as a hospital requirement, and the construction is of the best in materials and workmanship. The architects

were Rand & Taylor, of Boston, and the writer has acted in an advisory capacity. A brief description will be given here, and for a more detailed one, reference is made to Burdett's new work on hospitals.

The hospital consists of four buildings, three belonging properly to it, and the fourth, a surgical operating theatre, being designed for the special purposes of the medical college. The cut (Fig. 296) shows in part the exteriors of the four buildings. The material is of Pompeian brick of a mottled yellow-gray color, and the ornamentations are in a light-colored terra-cotta. The roofs are of light-red Spanish tiles. Their domed form is an outward expression of the fact that the interior construction throughout is of the "cohesive system," by which

leading to the pavilions, there are tiled floors. In the lavatory and bath-rooms, operating theatre, and conservatory or sun-room, and in all of the basements, the floors are of granolithic cement. The stairs are of marble, slate, or cement. The outer walls are hollow, and the plastering is upon the brick. The cost of the building, ready for use, will be something over one hundred thousand dollars, exclusive of the surgical building.

The plan of the first floor (Fig. 297) presents the arrangement of the wards and rooms with much detail, to which little need be added.

The entrance hall of the administration building, which faces the south, leads to a rotunda which is finished in marble and oak, with an appropriate tablet giving it a

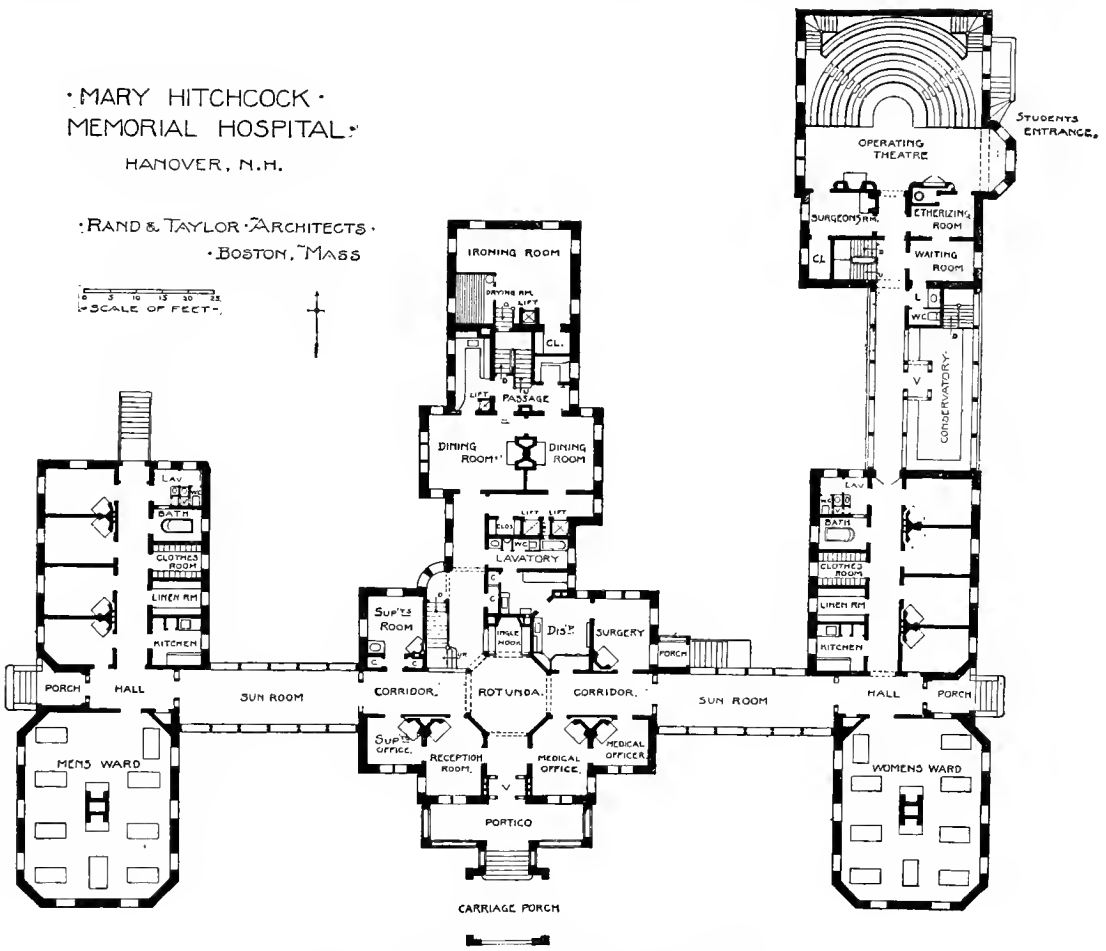

FIG. 297.—Mary Hitchcock Memorial Hospital. First Floor Plan.

all ceilings are formed of layers of vitreous tiles laid as shallow arches, or higher domes, over the rooms, and sustaining the floors above. This is an adaptation to modern use of the early Italian and Spanish dome-construction, and this building is the first in America planned especially for the modern application of this method throughout. The inner partition walls being all of brick, there is a unity of fire-proof construction, largely of vitreous and non-absorptive materials, including the outer walls. There is no iron or wood for the support of stairways or other construction, and only the floors and slight finishing around doors and windows are of hard pine, except where the woodwork is of oak, in the first and second stories of the administration building. Here, in the main hall, the first floor is laid in marble mosaic; and in the connecting corridors, serving as sun-rooms and

memorial character. The second floor contains eight private rooms in the main building, and the service rooms, etc., are in the rear extension, with an intervening cross lobby. The third floor has accommodations for twelve nurses. The one-story pavilions contain each a ward for ten beds and four private rooms; the capacity of the hospital is thirty-six beds. The ward, 28 × 36 feet, has an arched ceiling at the height of 13 feet, and while it has all the advantages of a round or octagon ward with a central chimney and vent-shaft, its general rectangular shape is better for convenience of service and arrangement of furniture. The bath-room and lavatory, with a screen between, form together a lobby surrounding the inner apartment containing the water-closet, etc. The surgical building has a high-domed roof, showing handsomely the tiled construction, in which are ample sky-

lights. The heating is by steam and indirect radiation in all wards and rooms. The warm air inlets are near the floor and mainly under or near to windows. The boilers are placed in a deep basement under the surgical building. The ventilation of the latter is by the chimney with a central smoke-flue. In the wards it is by the central chimneys also; elsewhere there are vent-chambers in the roof to which the ducts are led from the rooms. There are openings under the beds in the large wards, connecting with the base of the large chimney, and in other rooms near the floor and ceiling into ducts, which rise mainly in connection with the chimney stacks. The rooms for nurses and servants, in the second and third stories, are warmed and ventilated by the transom system, the warm air abundantly supplied in the halls enters through the open transoms, and after traversing the room, aided by the chilling it receives at the windows, makes its exit by vent-openings near the floor in the interior walls. The ventilation, as a whole, is accomplished by a simple and effective application of the extrac-

the St. Luke Free Hospital and the Michael Reese Jewish Hospital in Chicago. In England two especially interesting plans are those of the West Bromwich and the Swansea Hospitals. In Germany the Augusta Hospital at Berlin is particularly noteworthy.

The Presbyterian Hospital in New York is an important example of a recently constructed large hospital, it having been rebuilt and greatly enlarged since its destruction by fire a few years ago. It now has 315 beds in 30 wards, mainly in three pavilions of three stories each, with one or two subjacent stories used for other purposes. It is expensively and finely built, fire-proof, and at a cost of $875,000. Its arrangements are elaborate, and include a model operating pavilion, a dispensary, and pathological department. In the value of the land upon which it stands, its high buildings, and the consequent complexity of its heating and ventilating arrangements, it illustrates the tendency that sometimes prevails under such conditions, to depart from the rule of simplicity of construction. The Methodist

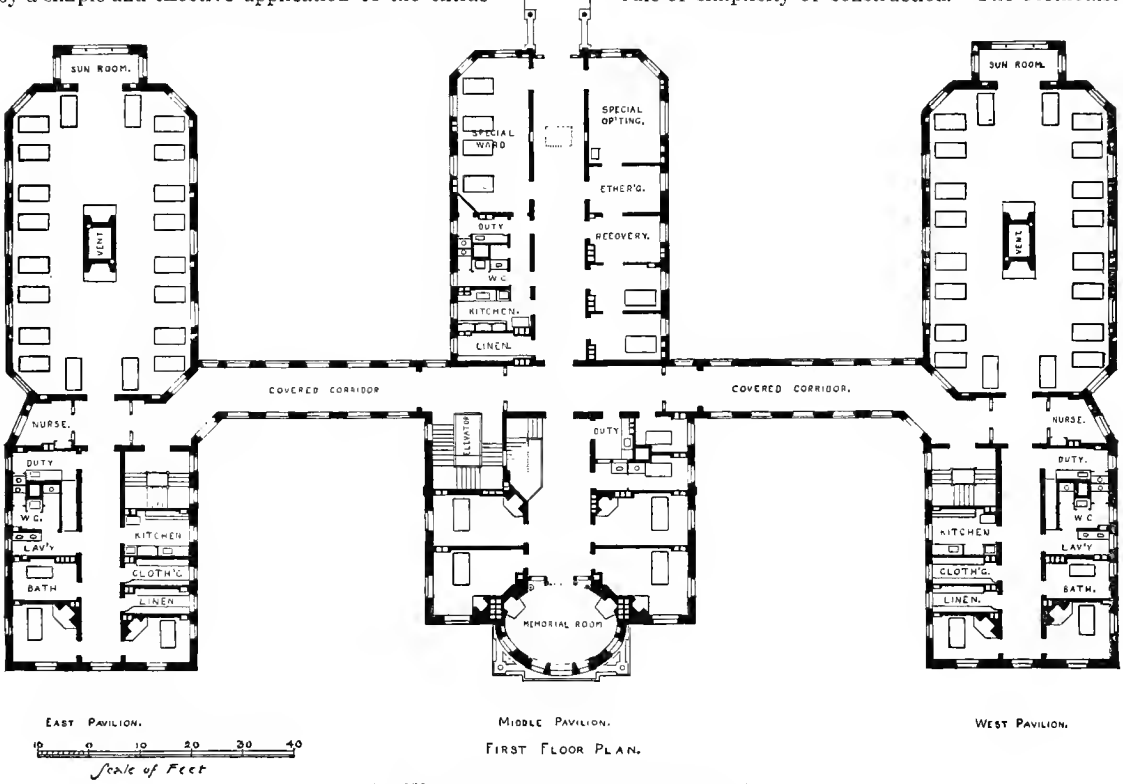

FIG. 298.—Memorial Wards, Pennsylvania Hospital.

tion system, and renders it easy to change the air of the wards and rooms at least three or four times per hour when desired.

The plumbing is fitted with the best modern appliances, all pipes and traps are exposed, and discharge into risers of soil-pipe in pipe-shafts which serve also for the ventilation of these special apartments. All water-pipes also have their risers in these shafts, the waste heat from those for hot water aiding the ventilation. The furnishing selected by Mr. Hitchcock is of the best materials and admirably suited to the strictest hospital requirements.

There are now, in this country, so many small hospitals of the class here illustrated that the mere mention of them would make a long list. Among the newer and notable ones are the Arnot-Ogden Memorial Hospital at Elmira, N. Y.; the Margaret Pillsbury General Hospital at Concord, N. H.; the Memorial Hospital at Worcester, Mass. Burdett gives some interesting examples of small hospital construction. Among them there are, in this country, Episcopal Hospital in Philadelphia is an excellent example of a two-story pavilion hospital built upon a plan admirably elaborated by Dr. Billings, and designed to accommodate, when fully carried out, 300 patients. The Presbyterian Hospital in the same city has some new surgical wards that well represent the strict application of the principles of construction of one-story pavilions.

The Pennsylvania Hospital has an excellent new house for nurses, and an out-patient department; and a new surgical hospital is now in process of construction on the grounds in Pine Street of this historic institution, which was built in 1750. There will be three separate pavilions built upon plans by the architect, Addison Hutton, in conference with the writer. The limitations as to the area and form of the lot, led to a variation from the generally adopted plan of construction in the pavilions, in order to utilize best the whole space for these and future structures, and preserve the pavilion principle. The buildings are of brick and granite, and harmonize with

the colonial style of the old hospital; they are so placed that their head-houses face in the opposite direction and toward the northern boundary of the lot, at a distance from it of twenty-five feet. The grade becomes lower here, permitting, for the central building, a carriage approach and an *entresol* entrance in the basement story, which is ten feet high. A large bay is formed upon this end of the building and affords a fine oval room on the first floor, which with this mode of entrance is treated to give a special memorial character to this part of the structure. Beyond this the basements are mainly used for purposes of ventilation and warming.

The first floor plan of the three buildings is given in Fig. 298. They are connected by a basement corridor which extends to the central part of the old hospital; the corridor forms a covered way with open sides between the pavilions on the first floor, and a terrace on the second floor. The distance between the buildings is 45 feet at the narrowest, and 50 feet where the large wards are. The sides of the buildings are free from projections. The central pavilion is of three stories; the rear half of the corridor on the first floor being a passage to the other wards, the adjoining rooms are arranged for special uses, and are not commonly occupied by patients. The memorial rooms and four special

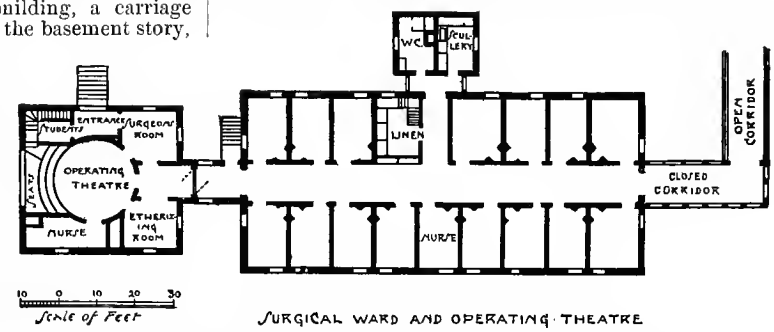

FIG. 300.—Bradlee Memorial Ward, Massachusetts General Hospital.

wards occupy the front end of the building. The east and west pavilions, two stories high, have each two large wards of 20 beds each, and two special wards, besides the service-rooms. The large wards are 35 by 60 feet, with a central chimney and vent shaft, and fireplaces. The height is 13½ feet, and the ceiling is somewhat arched at the sides and ends. It may be described as a long octagon ward with the advantages both of that and of the rectangular form. It is exposed to sunlight and air on the east, south, and west, and nearly all of its exterior walls.

The second floor of the central pavilion is shown in Fig. 299. This is for the gynecological service, with a large ward of 10 beds, and smaller special wards, an operating-room, etc. The third floor has a similar arrangement of rooms, to be used for women and children; the latter have two wards containing 19 beds. The total capacity of the three pavilions is 140 beds.

The floors of the first story and all rooms in which there is any water-service will be constructed throughout of iron beams and hollow bricks. The finish is to be plain and substantial with all angles rounded; marble and tiles will be freely used in appropriate places, including the operating-rooms, etc. All toilet-rooms have plumbing exposed, and are arranged with a central shaft for all pipes and for the independent ventilation of these special apartments which are cut off by a screened lobby from the main halls.

The heating is by steam and indirect radiation. Elsewhere than in the large wards, which have special vent-chimneys, the ventilation is by ducts leading to chambers in the roof. The outflow in all of these may be accelerated by heat from steam-pipes. The extraction system is applied in its simplest form, so as to work automatically with the smallest need of attention.

The demand for aseptic conditions in modern operative surgery has been met by the invention of special constructional devices in rooms to be used for that purpose. The first notable building of this kind was erected at the Massachusetts General Hospital, in 1888, as a memorial building. It is a one-story pavilion, and its plan is shown in Fig. 300. The building is approached from the other parts of the hospital by an uncovered way.

The ward itself has the general arrangement of rooms designed for isolation, the corridor between them being 8 feet wide and 24 feet high, with a monitor roof with many windows that may be freely opened. This gives the corridor, in relation to the rooms, the effect of their opening upon the outer air. The lavatory, scullery, etc., are outside of the building, with an intervening lobby protected at the side only by a screen. The passage is guarded by double doors swinging both ways. The heating is by steam and indirect radiation, the inlets being under the windows. These have transom lights over them. The ventilation is by an independent duct in the chimney for each room. The walls and ceilings are

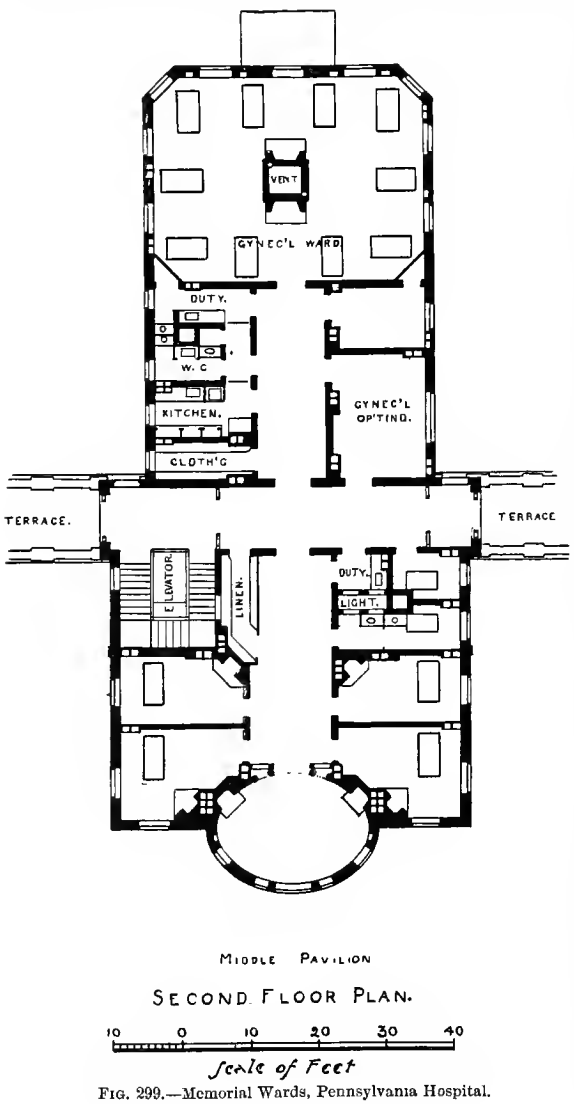

FIG. 299.—Memorial Wards, Pennsylvania Hospital.

painted, the floors are of hard pine, and the finishing in wood and plaster has all corners rounded.

The special feature of the building is the operating theatre. At the northerly end a door from the main corridor opens into a connecting lobby, which is divided midway by swinging doors. A door to the right opens upon a flight of steps intended for the entrance and exit of the hospital attendants. Beyond the swinging doors, one in front opens directly to the amphitheatre floor, one on the right to the surgeons' consultation-room, and one on the left to an etherizing-room. Doors from either room connect with the theatre. The walls are of pressed brick; the floors, like those of the corridor and theatre, are of asphalt.

The floor of the amphitheatre is circular in outline, with a diameter of 18 feet. Directly over this is a monitor roof of hammered glass, with an area of 280 square feet. Contiguous with this glass roof, at the northerly end of the theatre, is a window made of four sheets of plate glass, the combined area of which is 192 square feet. Beginning at either side of this window is a wainscoting of polished white Italian marble, continued so that it encircles the whole operating space. Above this wainscoting, and projecting over it, is the first circle or tier of the balcony, guarded in front by a heavy iron and brass railing. The balcony affords standing room for about one hundred spectators. Opening out of the amphitheatre, on the westerly side, is a general supply-room. The corresponding space on the easterly side is a passage-way from an outside entrance to a flight of granite stairs leading to the balcony. From this passage-way, through an arched opening in the marble wall, access is had to additional standing-room for twenty-five spectators. This standing-room is obtained by three semicircular tiers of marble and flagging, extending from the amphitheatre floor to the sill of the large northern window. The entire basement is concreted. It has no stairway connection with the floor above. The ward and theatre are lighted by electricity.

The gynecological department of the Johns Hopkins Hospital being found to need a place to be used exclusively for operative work, a building was erected for that purpose in 1891. It was placed conveniently near the private ward for women. A plan of it is shown in Fig. 301. Its convenient and simple arrangement, and its ingenious special devices, make it an admirable model of a fitting provision for its work.

The building comprises a large operating-room, 25.8 by 25.9 feet, the floor of which is covered with Sinsig tiles laid upon lime of Teil arches, and the walls are wainscoted to the height of four feet with Tennessee

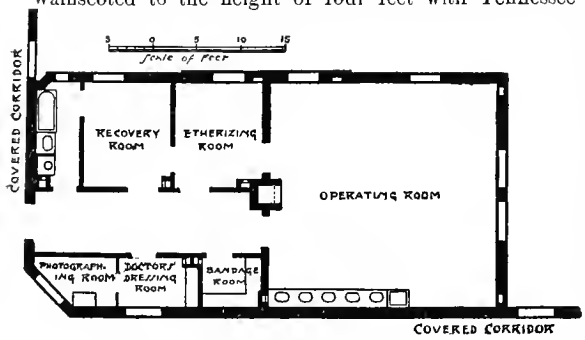

FIG. 301.—Gynecological Operating-room, Johns Hopkins Hospital.

marble. The walls are plastered with King's cement, which furnishes a hard, smooth, and non-absorbent surface, with little opportunity for the lodgement of infectious germs. Adjoining the operating-room is an etherizing-room, 10 by 12 feet. Communicating with this is a recovery-room of the same size, with an adjoining bath-room and water-closet. The building has also a supply-closet, dressing-room, and photographic room. It is heated by steam and ventilated by a shaft. The floor of the building is on a level with the floor of the main corridor, and the building is one story in height. The operating-room is lighted by two windows looking west, a large double window looking north, and a large skylight. The windows and skylight are of obscured glass, so that the light which enters is thoroughly diffused, and strong and annoying cross-lights are prevented. The interior lighting is both by gas and electricity. The structure is of brick, with a slate roof, and corresponds in general appearance with the other buildings upon the grounds. The only departure from the

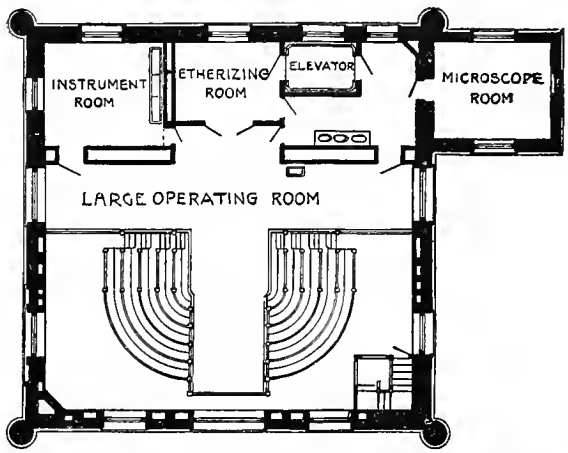

FIG. 302.—Presbyterian Hospital, New York. Operating Pavilion.

method of heating adopted in the remainder of the buildings was in the location of the heating flues at a height of six feet from the floor, it having been found by experience that this arrangement prevents annoying draughts of air upon patients.

The new operating pavilion of the Presbyterian Hospital in New York has just been completed. The seating capacity of the main amphitheatre is one hundred persons; it is in the upper story of the two in the building, and is shown in Fig. 302. It is finely lighted by large skylights and three great side lights on the north, south, and east. The wainscoting and floors are of marble, and the doors are heavy slabs of the same material. In the basement story, which is on a level with the corridor communicating with other parts of the hospital, there are two other operating-rooms to be used when seclusion is desirable; there are also a recovery- and an etherizing-room, and those for instruments, etc. This building is a remarkable example of the adaptation of stone and iron to special devices of construction, excluding the use of wood almost entirely.

The Roosevelt Hospital, in New York City, presents the most remarkable structure of this kind that is now in existence. It is the William J. Syms operating theatre, a memorial building for which the bequest was $350,000. It has just been completed and equipped at a cost of about two hundred thousand dollars, and the residue provides a fund for its maintenance. It is two stories high in front and three stories in the rear. The amphitheatre occupies the centre of the building, and is lighted by a glass dome with a northern exposure, admitting the rays of light above and behind the audience; as far as possible, the light that illuminates the operating-table is made to enter the room from behind the observer, and nearly parallel with his line of vision, with the exclusion of all cross-rays. The plan of the first floor may be seen in Fig. 303.

The architect was W. Wheeler Smith, but Dr. Charles McBurney, the Attending Surgeon to the Hospital, was made responsible, in the will of the donor, for the construction and equipment of the building.

The main entrance on Fifty-ninth Street is intended for the students of the College of Physicians and Surgeons that stands on the opposite side of the street. The broad

vestibule has a marble mosaic floor, and Italian marble is used for the interior finishing and the stairway leading to the upper seats of the amphitheatre. This has a seating capacity for 185 students, but 330 could easily be accommodated within its space if it were desirable to admit that number of persons to a clinic. The seats, in six tiers, are of wood, with wooden backs only; they are supported by being fastened to iron standards. A wainscot of pure white marble, 5 feet high, encircles the room at the top of the amphitheatre, while behind the operator an unbroken surface of marble rises from the pit to a line on a level with the top of the wainscot before referred to. Part of the pit extends backward to a recess lined with marble on every side, including its ceiling. The floor is of marble mosaic, and its immediate surroundings are finished in marble and iron. The steps leading to the seats of the amphitheatre are of slate. Under the seats the sloping surface is of asphalt over thin concrete on wire lath. At the top of the entrance stairway are two rooms, one for surgical records and the other for the house staff.

The front part of the building rises to two stories, and the central and rear portion to three stories above a basement. On the ground floor the outer rooms, east and west, are only one story high and admit light by skylights as well as by large windows in the outer wall, which, from their situation, have to be fitted with semi-opaque glass. The rooms are carefully and ingeniously fitted for the uses indicated in the plan; the instrument-rooms, for example, have cases of metal frames with glass doors, sides, and shelves, which were imported especially for their purpose; and there are many devices for promoting asepsis. An inclined plane has been provided, in place of an elevator, by which patients may be wheeled to the recovery-rooms, four in number, on the second floor.

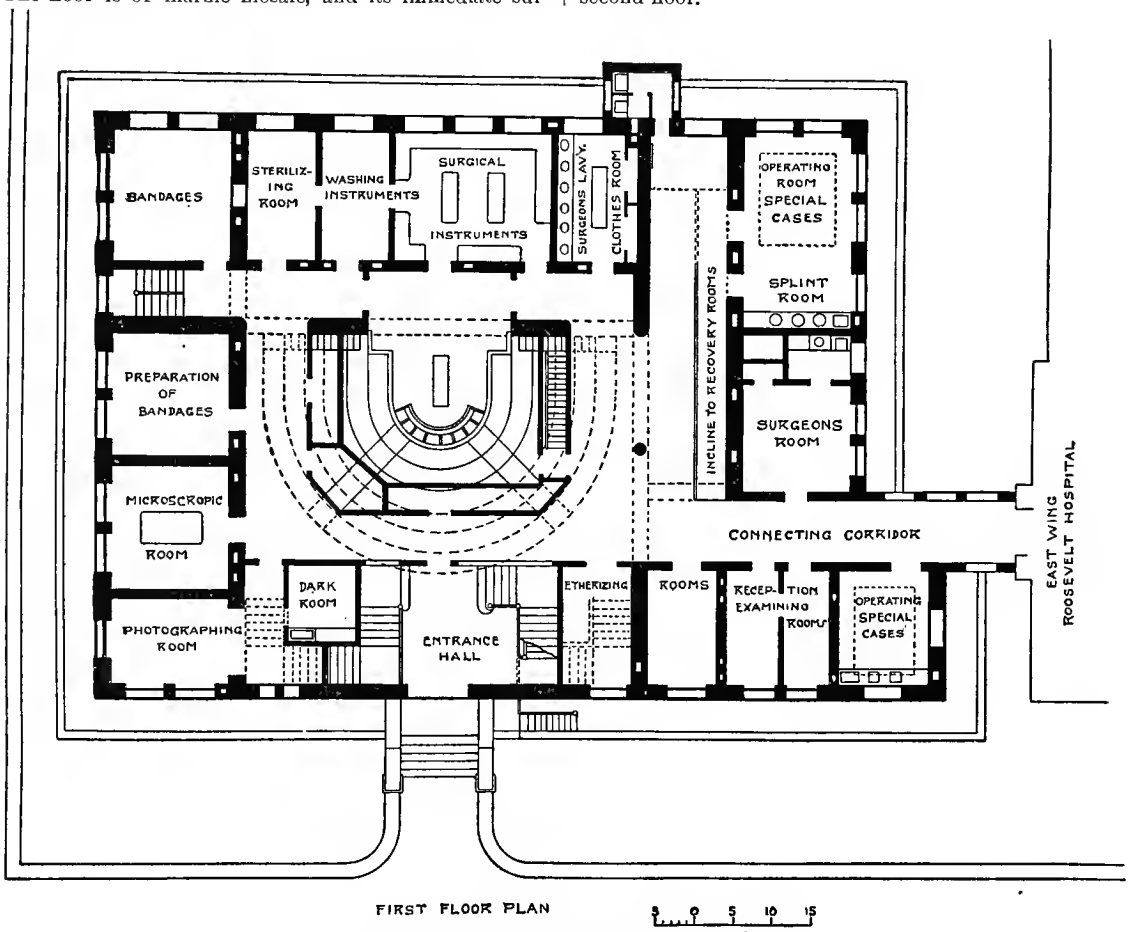

FIG. 303.—Roosevelt Hospital. William J. Syms's Operating Theatre.

A covered corridor leads from the Hospital to the first floor of the building, all of which is laid in marble mosaic with angles rounded to meet a marble wainscot 5 feet high.

Several of the most important rooms, where it is desirable to promote aseptic conditions, are fitted with doors of pure white Italian marble, 1¼ inch thick, hung on massive metal hinges, a single slab in each case forming a door. The special operating-rooms for septic and other cases are fitted with all conveniences, the interior and equipment being chiefly of marble, glass, and metal.

The amphitheatre, as indeed every other part of the structure, is supplied with gas as well as electric lights, to insure the building never being without efficient means of lighting.

The warming is by steam, the air, taken at an elevation of 22 ft. 8 in. from the ground, passes over steam pipes in great inlet ducts in the basement, and is forced by fans throughout the building; it is driven by one fan to the amphitheatre alone, and by a second fan to all other parts of the building.

Fresh air, either hot or cold, as may be desired, is supplied to the amphitheatre through one hundred four-inch cast-iron inlets, commercially described as goose-necks, penetrating the inclined plane under the seats and directing the air, as it is received from the chamber underneath, upon the surface of the inclined plane. Ventilation is by aspiration through a large register near the

ceiling, into a heated chamber which thence discharges its contents, at the highest point of the structure, to the outer air. In all other rooms of the building separate vent-ducts rise directly upward to their exit openings, like chimney-flues—a system which entails the risk of down drafts of cold air in some of them if a careful balance of the forcing and extracting power is not always maintained.

Mention should be made of the sterilizing apparatus, occupying a room by itself and adding, in a marked degree, to the efficiency of the agencies employed to promote asepsis. The building is a most notable one in its elaborate perfection and practical fitness for carrying the work of operative surgery to the last degree of refinement.

The rapid development in recent years of the relation between the hospital and the community is bringing it about that the hospital is less exclusively the refuge of the poor, but a "palace of health" for all. In a recently published book on "The Nationalisation of Health," Havelock Ellis advocates a more complete legislative control than is now had, of these interests in which the guardianship of life is concerned. It is his view that, "in the end every medical man in the country would be attached to a hospital, and every person would be living within the district of a great institution of health."

In England there is greater advancement in these matters than in America. But it may be that here the great ends of preventive medicine are to be gained in a different way, by the more general distribution of smaller centres of sanitary control, and the education of the local practitioner through the reflex influence of the local hospital in which he works. One needs to go no farther than Waltham to witness the invention, already referred to, of a new kind of training-school that is destined to popularize the principles of nursing as a matter of common knowledge and use, and to find also the beginning of a movement which should be successful there and elsewhere in bringing into the smaller cities and towns the life-saving appliances of a disinfecting station, of which there are too few even in the largest cities of the country. To the social economist, whose doctrine is that public health is public wealth, no more helpful aid has come than by the advancement of knowledge of the causation of disease, which teaches the means of prevention. A broader socialism, acting upon the highest motives of philanthropy, is being developed in like manner through better knowledge of the laws of life which must be obeyed to cure both physical and moral ills.

The admirable work of the Metropolitan Asylums Board in London stands as a model for the effective organization of hospitals and disinfecting stations for the protection of the poor, and the whole community alike, from the dangers of infectious and contagious disease. It has been demonstrated by experience that the value of a permanent isolation hospital is in its providing the means of isolating at once the earliest cases of disease, and thus preventing the epidemic, instead of leaving it to be battled with when it has got full sway. In Burdett's work the admirable chapters on this subject are most instructive. Valuable and precise information as to the best methods may be found in this work, and in Dr. Thorne's report "On the Use and Influence of Hospitals for Infectious Diseases," which forms a part of the "Tenth Annual Report of the Local Government Board for 1882." Among the plans given by Dr. Thorne is that of the Warrington Hospital. As a good type of such English hospitals, a plan of one of its small pavilions is shown in Fig. 304.

A common arrangement is to group together a number of such small pavilions, and to connect them by a covered way, open at the sides, with an administration block.

The Warrington Hospital is of brick; its arrangement is shown in the block plan, Fig. 305. There is a two-story administration block, *a*; two ordinary ward pavilions, *w*, *w*; a special detached pavilion with like interior arrangements, except that its wards are reduced to a capacity of one bed each, *w*; a lodge at the entrance, *e*; and two groups of out-buildings, *b*, *d*. One of the latter contains a laundry, disinfecting chamber, ambulance-shed, mortuary, and store for wood, coals, etc.; the other contains two hand-vans to be used in connection with the stove, and a store for garden tools, etc. These forms of pavilions are two of the four prescribed by the Local Government Board.

The disinfecting apparatus is a "Ransome stove," otherwise well known as the Nottingham self-regulating

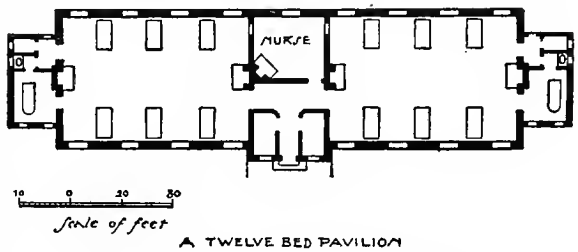

FIG. 304.—Warrington Infectious Diseases Hospital.

disinfecting apparatus, in which articles passed through it are subjected to a temperature of 250° F. by dry heat. It consists of a cubical iron chamber encased in wood with an intervening layer of felt, access to the interior being had by double doors. For disinfecting stations the chamber has doors on opposite sides, and is placed in the partition wall between two rooms, an "infected" side into which articles are carried, and a "clean" side from which they are removed. The furnace is placed at a lower level, and heat is generated by burning gas. There is an automatic regulator. A full description is given in Dr. Thorne's Report, pp. 210 to 214. An approved form of apparatus employing steam confined under pressure, is Lyons's patent steam disinfector, one of which is in use at the Johns Hopkins Hospital. This is an expensive apparatus and somewhat difficult in its method of working. These and other forms of appara-

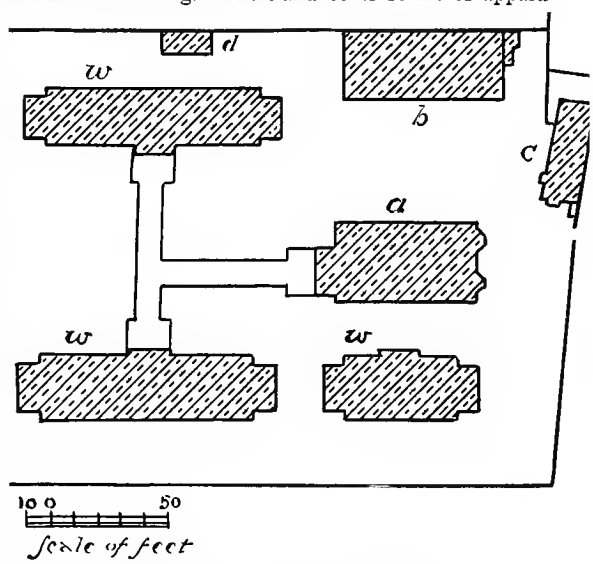

FIG. 305.—Warrington Hospital. Block Plan.

tus and experiments in testing them are described by Dr. Parsons in his report on disinfecting by heat, to the Local Government Board, in 1884.

The Fever and Small-pox Hospitals of the city of Glasgow form an extensive establishment, which was completed in 1887. The Small-pox Hospital has ten wards in five pavilions, and the Fever Hospital has twenty-six wards in thirteen pavilions. The pavilions are of one story and are alike in form and arrangement; they are detached and arranged in groups with respect to their

isolation, and to the administration and service buildings. One of these pavilions is shown in Fig. 306. The two hospitals occupy a country estate of 33 acres, with large gardens and pleasure-grounds, at Belvidere. The Fever Hospital was begun in 1870, the first pavilion being of wood. In 1879 the erection of brick pavilions was begun, and now all are substantial structures of that material. Ample and excellent accommodations are furnished for physicians and nurses. The cost of the Fever Hospital was about £76,000. The Small-pox Hospital is

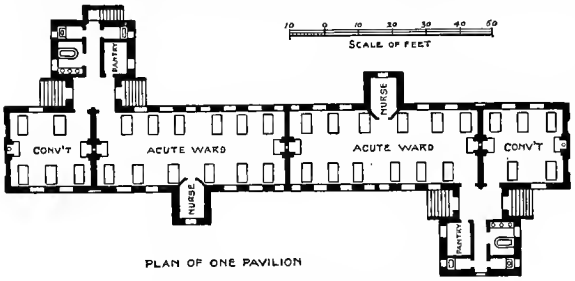

FIG. 306.—City of Glasgow Hospital.

completely isolated by a boundary wall. The whole cost of it was about £30,000. A remarkable reduction has been made in the death-rate of the city since the opening of this hospital, due to a variety of causes, not the least among them being the efficient labors of Dr. Russell, the Officer of Health. This hospital affords the most striking demonstration of the profit of guarding the public health.

The Cambridge Hospital, in Massachusetts, has recently received an addition of a building for infectious and contagious diseases. It is on the grounds of the hospital, at an effective distance from it, and near the bank of the Charles River. The material is brick, and the symmetrical halves of the building are so arranged as to be entirely independent, and without means of communication except by going around the house, out of doors. It is of one story, except that a nurse's room in the attic for each section is accessible by an outside stairway.

The plan is shown in Fig. 307. The construction is simple and substantial, as designed by Dr. Wyman; it is for the treatment of diphtheria, scarlet fever, etc.,

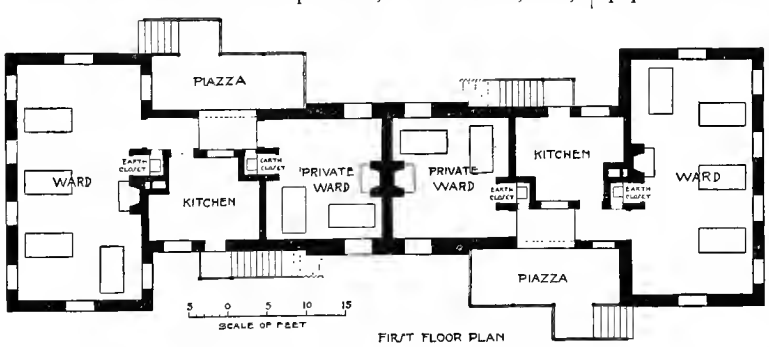

FIG. 307.—Contagious Disease Ward, Cambridge Hospital.

such cases as may occur in the hospital, or may be received from the vicinity. This plan is a modification of one of those of the Local Government Board already referred to. Here it is improved by entrance lobbies to the wards, more windows, and access to closet without exposure in cold weather. A bath-room would further improve it.

An interesting example of a building for isolating the cases that may require it, occurring in a large hospital, is to be seen at the Presbyterian Hospital in New York. The plan is given in Fig. 308. It is situated within the hospital enclosure in the limited area of a paved court. At the level of the main floor, shown in the plan, there is an outside platform or balcony from which there are separate entrances to the rooms, for four patients, occupying the corners of the building. From the ground level the balcony is reached through an opening therein, and by a stairway. The serving-room in the centre of the

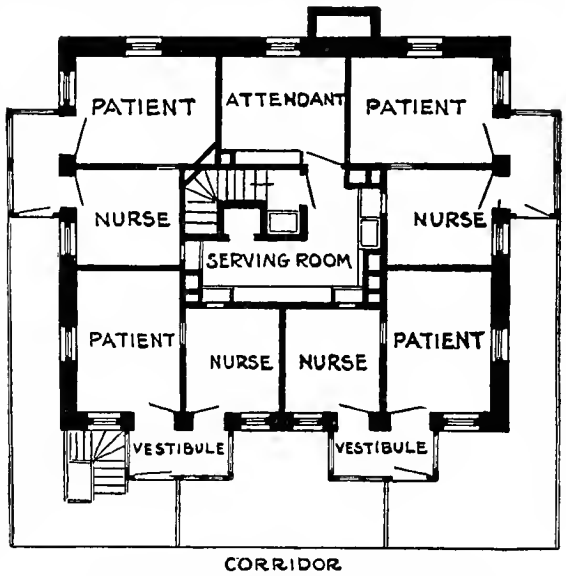

FIG. 308.—Isolated Pavilion, Presbyterian Hospital.

building, and that of the attendant in charge of it, are accessible only by way of the basement.

The Boston City Hospital is now being enlarged by a new and important hospital for contagious diseases. It is known as the Chester Park Hospital, and is subject to the limitations of a city lot. It is to receive cases occurring in the wards of the hospital proper and from the city at large. There is requirement for its accommodations to be centrally situated in so large a city, rather than in any suburban locality that is available, which would be at a great distance from the major part of the population it serves. It is a handsome structure of brick, consisting of six principal buildings, with the adjuncts of a boiler-house, laundry, and morgue, and room for a small pavilion to be added in future. These adjuncts are not shown in the first-floor plan, which is given in Fig. 309. In the lettering of the plan *B* is bath-room, *D* duty-room, *E* elevator, and *O*, operating-room.

The plans were designed by the city architect, Mr. Wheelwright, in conference with Dr. Rowe, the superintendent of the hospital, after an extensive study of the subject, and with the approval of its medical staff.

The entrance gate is at the centre of the one-story lodge, which all persons who enter the hospital must pass through. The administration block, occupying a central position, is three stories high, and contains offices, and quarters for officers, nurses, and servants. Covered passageways, with open-air walks over them on the first-floor level, connect the basements of the buildings. The domestic building in the rear contains the kitchen, etc.; a dispensary, and a dining-room for servants, their chambers being on the second floor. A nurses' home, not shown in the plan, is a detached building to accommodate sixty nurses.

The wards are in two pavilions, each two stories high, and are designed to accommodate 136 patients, including men, women, and children. At the junction of the communicating corridors with each pavilion there are steps

leading up from the ground level to the first floors, and others to the basement floors underneath. Here there is an open way across the corridor from side to side, at the basement level, disconnecting the covered passage in the corridor from the building.

The conditions for the treatment of patients in these wards require a classification, not only regarding the sex of patients and their being adults or children—permitting the latter to have their mothers with them in some cases—but there must be proper provision for isolating extreme cases of each of the special forms of disease, and the varying and numerous complications of different contagious diseases. This grouping and isolation of patients is accomplished by the division of each floor into four wards. There is an open ward of ten beds, and four beds in three rooms, in the rear section. This large ward is for convalescents and looks southward. This section is separated from the middle section by a cross corridor, opening broadly to the outer air at each end. An isolated stairway, starting from the outside of the building, here leads to the second floor. The middle section is, in like manner, isolated from the front section, which also is divided in two parts in the same way by a broad opening leading to a wide loggia on the front of the building. Here are the two small probation wards near the front entrance. The floors of these rooms are of asphalt, the walls of white enamelled brick, and the ceiling of Keene's cement. They have their own service- and bath-rooms, as does each section of the whole building. The walls of the isolating passages are also lined with enamelled brick, have mosaic flooring, and cement ceilings. The toilet-rooms are finished in like manner, and are surrounded by an air-space like a lobby, isolating them from the main hallway. The plumbing fixtures of each section are arranged around a shaft affording independent ventilation for these apartments, and a pipeway for all waste and supply pipes. Each section has its own linen and medicine closets; and the shutes to the basement for soiled clothing are from the open-air cross corridors.

The basements, reached by separate staircases from each section, contain the rooms for patients' clothing. At the entrance to the building, in the basement, is a series of rooms through which all visitors must pass. In the first room the outer clothing is left; thence by a lobby another room is entered where a gown is put on to be worn while visiting the sick. On returning, this gown is left in a room on the opposite side of the building, and thence through another lobby the visitor reaches the first room, where the outer clothing is resumed. Like precautions are exercised by the attending physicians.

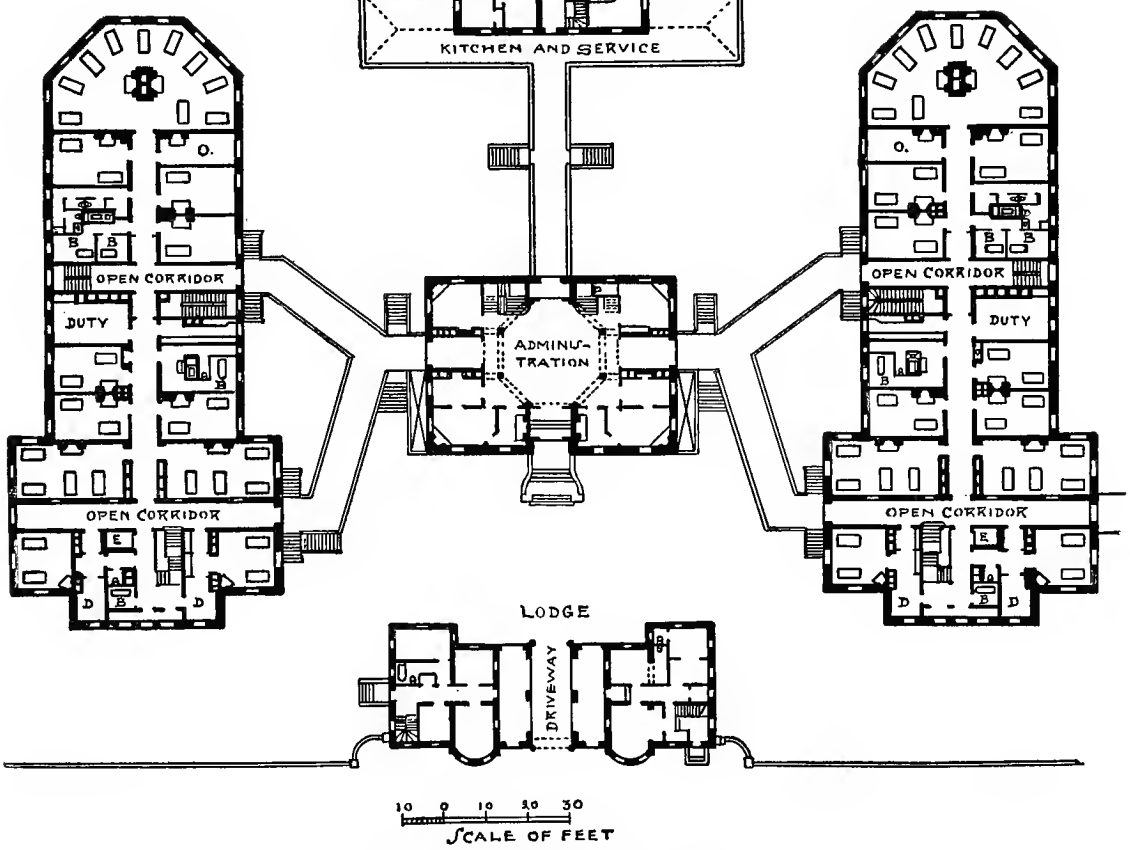

FIG. 309.—Boston City Hospital for Contagious Diseases.

The heating is by steam and indirect radiation. Each room has one or more ventilating outlets, one near the floor and ceiling for every duct in each room. These ducts lead to a vent-chamber in the roof for each division of the building. The whole lot is enclosed by a brick wall eight feet high.

The application of sanitary science has made very slow progress in America, considering the great advancements in knowledge of the causation of disease. In the few States and cities where attention has been given to this subject, experience has shown the necessity of governmental control of sanitary matters. The work of the States of Massachusetts and Michigan in this regard has reached a development of methods that ought to be fol-

lowed in every State. A department of public health, to be established by the national government, is the demand of the time.

The definite knowledge that has now been gained by the scientific tests of disinfection establishes a basis for its practical application. According to Parsons, Sternberg, Blyth, and others, heat is undoubtedly entitled to the first place among the agents available for the destruction of infectious material external to the bodies of living animals. In nearly all the important infectious diseases of man and the lower animals, it is safe to assume that the temperature which kills the tubercle bacilli, 212° F., will be sufficient to accomplish disinfection. Ample allowance is made, in directing the disinfection of all kinds of infectious material, by subjecting it to a boiling temperature for half an hour, either in water or steam. Exposure for ten minutes to steam under pressure to raise the temperature to 221° F., will accomplish the object. The fact that the spores of certain bacilli found in the soil resist a considerably higher temperature than this has led to undue exactions in the use of heat. Esmarch has shown that dry heat is less effective than moist heat, superheated steam being less so than streaming steam at 212° F. Exposure to the moist heat of steam at twenty pounds pressure—temperature about 230° F.—destroys the most resistant spores in twenty minutes. A temperature of 240° F. is effective almost immediately. The simplest way of disinfecting articles of clothing and other articles not injured thereby, is to immerse them in boiling water. Cholera germs are killed at 126.6° F., and typhoid germs at 138.8° F., by exposure for four and ten minutes, respectively. Infectious excreta of these diseases may be disinfected by adding three or four times their amount of boiling water. Sulphate of iron or chloride of zinc, in solution therewith, will deodorize and disinfect at the same time. This is a good rule for domestic and hospital use. The chemical disinfectant that is of practical value, and prompt in its action, is good chlorinated lime, which should contain at least twenty-five per cent. of available chlorine. A solution in the proportion of six ounces to one gallon of pure water being made, one quart of it may be used for the disinfection of each discharge in typhoid fever, cholera, vomited matter, etc. Then the contents of the vessel being well mixed, it should stand for at least one hour before they are thrown out. Infected sputum should be discharged directly into a cup half full of the solution.

The warming and ventilating of hospital wards is rightly regarded as a matter of great importance. The history of the subject, for the last thirty years or more, shows some curious changes of usage. There had previously come about the development of very complex systems in large hospitals, and particularly in asylums. Forced distribution of air, and ventilation aided by the propulsion of a fan, were much in vogue. The experience in military barrack hospitals, and in those of the simple construction that followed, taught hospital men the effectiveness of natural means when employed in the use of simple constructional devices, under the laws governing the movement of heated air. Very satisfactory results were gained by the adaptation of the principles of the extraction system, by means of vent-chambers and chimneys, even in such establishments as the Massachusetts General Hospital, Boston City Hospital, and Johns Hopkins Hospital, without the use of fans. It is perhaps through some failure to apply correctly the methods found so effective there, that there appears to be a reviving tendency to resort to mechanisms driven by steam power or electricity for the propulsion of warm air into buildings, or for extraction of foul air. The practical fact is that the more machinery there is, the more the trouble from defective working, inattention, or ignorance in managing it, or its disuse after a time as ineffective or too expensive. The best way is to devise a simple system that will work if let alone, or requires the least possible interference. It is only necessary to follow the simple law that a body of air relatively warmer than that which surrounds it will rise. Let it be conducted from the room to be ventilated to a chamber at a higher level, so that a body of warm air is held at a point intermediate between the room and the outer air. Artificial heat may sometimes be an aid in giving that chamber the requisite excess of heat. Under these conditions the chamber will discharge itself upward and outward through proper openings, without any danger of the reversal of currents downward through the ventilating ducts. Such reversals will occur in vent-ducts that open upward like chimney flues. Difficulty often arises simply from making the air-ducts and chambers inadequate in size, or attempting to combine too many ducts, of different lengths, in one system.

Hospital management comes next in order after the hospital is gained. A good hospital may become a bad one by bad keeping. Administrative troubles are often relatively worse and more disastrous in a small institution than in a large one; when there is a tempest in a teapot there is no room even for a small tempest. In the organization of the small hospitals the same principles should be regarded as in the larger ones; there should be only one resident head of the administration, and all other resident persons should be subordinate. This is a simple business principle, and it is remarkable that intelligent people of business experience will, as trustees, try over again experiments in organization and control that have so often proved the error of departing from a fundamental principle. It requires experience in the governing board, as in any other business, before this special business can be understood.

The small hospitals are being successfully managed by women trained in nursing, and who become skilled in executive work by doing it. The paramount object of the hospital is the business of caring for the sick. The position of the skilled nurse at the head of a small hospital is precisely the same in principle as that of the medical superintendent of a large one. The maxim of Dr. Mouat is equally applicable in each case: "Those are best qualified to conduct a business successfully who are best acquainted with its requirements."

There are two special sources of trouble—fundamental conditions from which trouble and failure are sure to come some time or other. They are either faults of the system, which even good people cannot get on with; or faults of the individual under a good system. It is true that a dual arrangement is sometimes successful; that proves the goodness of exceptional persons. Again, when the organization is correct in principle there are examples of the failure of individuals in executive capacity and tact, and the governors proceed to change both the individuals and the system. A vast amount of heart-breaking care and trouble could be saved, and disaster averted, in a struggling hospital that means so much to the community that supports it, by the recognition of a simple truth. There should be one head of every hospital household, who, under the controlling board, should have the sole and entire direction of its business. That head should be a person educated to the business, a medical man or woman, or an educated and skilled nurse.

There is one fundamental element in this matter that strangely appears never to be recognized as it ought to be. It is something more than the recognition of the business principle of the executive head. It is worth the utterance of many words to get it made clear, for the sake of the helpfulness it may bring to many a devoted and hard-working hospital officer, whose life is one of trial at the best. This fundamental principle is that, while the management of a hospital is a business, it is not like the business of managing a factory, or a mercantile house. The hospital, besides being the *place of business*, is the *home* of all the people in it. The household element is there; it is a family. The head of the family has a personal, protective relation to its members, controlling their peace and comfort. The fundamental rule therefore is, never disregard the principle of family headship in the hospital household. This applies alike to the man or woman who is at the head of it. A woman superintendent should be a trained and skilled nurse to

begin with; she should have executive capacity; and she should be helped by affording her time in the work to gain the efficiency that only experience can give. All other persons in the hospital should be subordinate to her. After this is done there remains one most important principle to be regarded: give the superintendent full authority, and hold him or her responsible for all that happens, but afford a chance for the exercise and protection of the responsibility. Above all things, the subordinates should not be meddled with, they should be managed only through the head of the house. This is perfectly safe, for they can always be accorded the right of appeal. Then it is fair, and only then, to expect successful work from the executive officer; and then, if there is failure of a well-supported officer to get good results, it is the fault of the individual alone, and the course to be pursued is plain. By such a plan of organization the relations of all concerned are made definite and intelligible, and there is no going against nature and the family principle, which always underlies the mixed organization of a civil hospital. *Edward Cowles.*

HOSPITAL STEWARD, DUTIES OF, IN THE U. S. ARMY.—The Hospital Steward is the executive officer of the hospital, in the post and in the field. Under the supervision of the medical officer, on the steward devolves the care of property, the maintenance of official records and correspondence, the management of food supplies, the dispensing of medicines, the extraction of teeth, and the application of minor surgical dressings. He fills the place of the house physician of a civil hospital in minor accidents and emergencies; he is responsible for the instruction and discipline of the members of the hospital corps under his command; on his vigilance largely depends the zeal and efficiency of the cook, nurses, and other attendants; he must see that all orders are obeyed, all work fairly apportioned and properly done.

To fit a steward for these multifarious duties he must have served at least a year in the line of the army, than which there is no better school of discipline; he must have served at least a year as a private of the hospital corps, and at least another year as an acting hospital steward. He is given access to works on chemistry, pharmacy, anatomy, and minor surgery. For his instruction there is a Handbook for the Hospital Corps, The Soldier's First-Aid Handbook, and The Drill-book for the Hospital Corps. He can study Army Regulations, General Orders, and Circulars, and the blanks for the various reports. Beyond all these there is still much to be learned that has heretofore been left to haphazard observation of the methods—not always the best methods—of the stewards under whom he has served. Unwritten tradition perpetuates error, shackles truth, prevents progress; to gather and arrange these neglected trifles, to till the ground uncovered by the above-mentioned literature, is the aim and scope of this article.

I. In Garrison.

The Routine Duties of a hospital steward in the United States Army intermit for sleep, remit for recreation, but are practically one continuous round. Where the cares of the passing day overlap the prospective duties of the morrow is a good initial point for their survey. We will begin with the

Meteorological Observation, taken at 6 P.M., and entered at once in the Register and on the Blank Report which is to be forwarded at the end of the month to such Weather Bureau centre as may be directed for the station. Both must be kept neatly; there will never be a more leisure moment. Scratch-block memoranda are so much extra work, increase the chances for errors, and are a useless waste of time. After the last observation for the month, totals and averages are computed on the Register and Blank separately, results compared to detect errors, and both are ready for signature.

After recording the meteorological observation the events of the day will be recalled to discover any possibly unfinished business—to be completed now. The desk is put in perfect order, with an eye for memoranda possibly overlooked. As far as possible to-morrow's Morning Reports for the sick and for the hospital corps will be prepared. In a blank-book, ruled as in Table I., are entered the names of all the sick remaining, or taken up during the day, arranged by organizations.

Table I.

May 15, 1900.

Name.	Rank.	Co.	Reg't.	Dis.	Diagnosis.	Treatment.
Stein, Jacob ..	S. M.	..	8 C.	H.	Sprain R. ankle. Misstep on parade.	Hot water; bandage; rest.
Pugh, Henry..	O. S.	..	G.N.C.S.	Q.	Powder burn R. hand and cheek. Def. primer.	Ext. grs. carb. oil, 1–40.
Atkins, Peter..	C.	I.	24 I.	H.	Ac. diarrhœa ...	Ol. ric., ½ oz.; tr. op., ♏ xx.
Jones, John...	P.	A.	9 C.	D.	Toothache	Ext'd R. U. A. molar.

This book is for convenience, and the following abbreviations are admissible if care be taken not to transfer them to the permanent records, viz., H., Hospital: Q., Quarters; D., Duty; G. N. C. S., General Noncommissioned Staff; P. Q. S., Post Quartermaster Sergeant; O. S., Ordnance Sergeant; C. S., Commissary Sergeant; S. M., Sergeant-Major; H. C., Hospital Corps; H. S., Hospital Steward; B. L., Band Leader; C. M., Chief Musician; S., Sergeant; C., Corporal; P., Private; F. Farrier. For regimental designation cardinal numbers are as good as ordinals; d, nd, st, and th consume time, occupy space, and obscure the record. 1 A., 3 C., and 8 I. are sufficiently distinctive for First Artillery, Third Cavalry, and Eighth Infantry.

If to-morrow will be the 10th, 20th, or last day of the month, Ration Returns will be prepared as far as practicable; also, if the last of the month, the Requisition for Fuel, Forage, and Straw.

"In the gloaming"—from six to seven o'clock—is the best hour for effective work, an hour of quiet and freedom from interruptions. If, habitually, all possible work is done at this time, daily tasks will be so lightened that fatigue will not now unfit for close application. With all work complete, the steward will have an evening for reading or recreation. With an assistant to put up the prescriptions that will come straggling in toward tattoo, he can safely leave the hospital.

Just before going to bed a look through the building and about the grounds must be taken. If anything be amiss, the proper man will be called to adjust it. The steward will do nothing himself; if he goes about at night putting out lamps, securing gates, and locking doors, his detachment will soon depend upon his vigilance, and negligence will grow apace.

The steward must see that helpless patients have provision for all their needs during the night; must satisfy himself that all—patients and members of the detachment—are present and in their proper places. Let everyone feel that absentees will surely be detected and reported. The hours allotted to repose are none too long; and effective work by day cannot be expected from men who travel about by night.

From Reveille to Surgeon's Call.—The presence of each member of the detachment must be verified. Breakfast is now on the table; consider its quantity, quality, and variety. The steward must see that the men who come to the dining-room are fully dressed, neat and soldierly in appearance. A bright dawn betokens a clear day; and men who habitually start right in the morning will rarely need correction before night. The patients must be counted, and each receive a careful scrutiny. There may have been changes during the night requiring an immediate report to the medical officer when he comes. Men in collapse, small-pox eruptions, and many other things ought not to await the surgeon's visit at a later hour. The steward will see that

the ward is properly warmed and ventilated, and have corrections made at once. Conditions, not seasons, must be the guide. After a cold rain in July, the ward may be chill and damp, and fire be as essential as in December. Quiet throughout the hospital will be enforced. Reveille is not sounded for the very ill. Undisturbed rest in these early morning hours may turn the scale toward health in critical cases. Let the invalids sleep; their breakfasts can be kept for them.

The steward now takes a complete survey of the building and grounds, and gets the general run of the hospital work. Frozen water-pipes, defective flues, things done improperly or left undone the day before, are all proper subjects for consideration in his early morning round. Each attendant knows his allotted task and will be doing it now; but the steward's judgment will be tried by never-ceasing variations. Each contingency must be met with prompt decision. If many helpless patients await their morning toilet before breakfast, the regular nurse is supplemented by utilizing the more intelligent convalescents and as many attendants as may be necessary. If snow-drifts are to be cleared away before Surgeon's Call, the man who attends to the outside police must be reinforced by other attendants, and less important work delayed.

A good beginning will save much trouble and annoyance throughout the day; but inattention to these duties may bring trouble and humiliation later. Should the steward offer for the surgeon's signature morning reports showing all present and learn later that a member of his detachment, or a patient, had been arrested in town during the night and was still in jail, he would justly forfeit the confidence of his superiors.

Surgeon's Call.—On the desk is the suitably ruled blank-book containing a list—arranged by organizations—of all excused from duty yesterday on account of sickness, with the rank, company, and regiment of each. An interrogation point in the appropriate column tells for which men a diagnosis is needed. As the Company Sick-books are brought in, they are compared with the hospital list and new names entered below. Care must be taken to get the full name, correctly spelled. This is specially important with the Sick-book for Prisoners; for sergeants of the guard are apt to know the prisoners simply as Brown, Jones, or Johnson, and so enter them in the book. Now, there may be several Browns, Joneses, and Johnsons in the command, and confusion may sometimes deprive a deserving man of a pension, or blot index and register with unseemly erasures. The time to settle doubtful points is now.

As the men are called in by the medical officer, record is made of whatever treatment may be directed. Should a new case be one of injury, what the man says was the cause is noted, also the limb or location, whether on the right or left side. These points are difficult to remember for even a short time; and now that outline cards are prepared for every recruit, the correct location of each new scar is important. Should a case be returned to duty with an interrogation point in the column for diagnosis, the medical officer should be asked for one now to complete the record. Should the man go away without this, the medical officer may forget the case entirely or confound it with some other, and great injustice may be done. In the column for disposition is entered a Q., H., or D., according as each case is marked for quarters, hospital, or duty.

Before returning the Company Sick-books to the first sergeants, an entry will be made of the numbers taken sick, returned to duty, or otherwise disposed of, in the proper columns of the Morning Report for Sick and Wounded. Each organization has a line for these entries. The sum of those remaining from yesterday and the new cases must equal the sum of those remaining, returned to duty, and otherwise disposed of. Footing the columns a like equality must exist between the totals. This double system insures accuracy; and now is the time to adjust discrepancies. It is humiliating to make errors in a report that is prepared every morning, and awkward to make subsequent corrections. If the post surgeon does not attend the call, the Morning Reports are sent to him for signature, and then to the Adjutant's Office. The steward must be prompt in this, for the sergeant-major compiles a Post Morning Report from these and has many other things to do before guard mounting.

Patients taken in Hospital must now be assigned to a ward, put in bed, and given such other treatment as may have been directed; those marked "quarters" are, presumably, better able to wait. For convenience of nursing, if there is more than one ward, it is well to place the more serious cases together. Among all men there are social affinities worthy of consideration. Sick "birds of a feather" do better if their gregarious tendency is respected. The victims of indiscretion—the men whom common frailties bring to hospital—should usually be gathered into one ward. The influence of example may be remotely beneficial—the mote in our neighbor's eye is frequently a useful guide to our own ocular defects. Men with barking coughs or noisy delirium must not be allowed to disturb the rest of critical cases of fever or pneumonia—the pay-day penitents are better able to endure this annoyance; and it may be better to so accentuate the bitter dregs from pleasure's cup. When the rosy-cheeked music-boy is brought to hospital, he will not be sandwiched between the reckless or the depraved; he will be better near that staid old sergeant whose grizzled hair and furrowed cheek may recall happy memories to cheer him in his loneliness—may inspire him with hope and courage to tide him over the hour of danger. The old man's friendship, now formed, may prove a useful ballast to the youthful bark throughout life's voyage. It is useless and unwise to be an outspoken reformer; but by attention to such details the steward can silently contribute his mite toward making better men, better soldiers. In a ward containing several helpless patients, to lighten the labor of the nurse and insure increased comfort for the sick, one or two convalescents may be utilized.

As a rule the American soldier is cleanly in his habits and does not need a bath upon admission; in exceptional cases it is for the steward or surgeon to decide. If this duty is delegated to a nurse, sooner or later a case of fainting and death in the bath-tub will bring sorrow. After men come under medical charge the steward is responsible for their condition and should see that they have a full bath once a week, in addition to daily ablutions. In all serious cases the directions of the medical officer must first be obtained.

Personal attention must be given to the effects that each soldier brings into hospital; and an inventory entered in the register for that purpose. The steward should be able to testify, from personal knowledge, what articles of clothing or other property are brought into the hospital; for, if the soldier has sold it before, he may claim to have lost it after, admission. Money, watches, and other articles of value must be enclosed in a suitably marked package and given to the post surgeon for storage in the hospital safe. If they so desire, patients may retain their money, at their own risk; but a nurse must never be exposed to the suspicion or temptation of picking the pockets of a drunken or delirious patient. Before leaving the hospital each patient must sign the Register as an acknowledgment that he has received all of his effects.

The Sick in Quarters will now receive their prescribed treatment. This is always an unsatisfactory class. The expenditure of medicines is much greater, the results less by far, than for an equal number treated in hospital. The steward can do much toward obviating the difficulty. If possible he should see that one dose is swallowed at the counter; he will dispense a quantity just sufficient for the twenty-four hours; will give directions clearly, both orally and in writing. Salts, salicylates, and many other drugs can be dispensed in powders, to be dissolved, when taken. If a bottle be necessary its return to-morrow will be enjoined; the contents may be poured on the highway, but the hospital will in this way recover a few vials. If only a second dose be required, it is

generally better to have the man come to the dispensary for it when needed. A stimulant narcotic, like Squibb's mixture, must be dispensed with great caution as to quantity; a toper may poison himself by taking all at once. Ulcers and abrasions will be dressed occlusively, so that the steward can tell if the dressings have been disturbed when the patient returns to-morrow. He will not improve its condition if he has access to it, and a small ulcer is sometimes considered less inconvenient than a detail with water-wagon or ice-cutting party. As the medicines are dispensed your list must be checked carefully, so that those who do not wait for their treatment may be reported to the surgeon. Care not to report the wrong man is important. The steward must treat all courteously, and never show signs of suspicion; to subject a sick man to unjust doubt is cruelty; to caution a malingerer is to render discovery more difficult. It is well to provide for the lame men last, and watch them depart; the non-commissioned officer has gone, long ago, and some of them may not limp all the way to their quarters.

After providing for the last sick man, a second round is made to see that everything is now in readiness for the surgeon's visit. The cook is told how many men are to be fed, and given orders for what he requires. Prepared for the post-surgeon's signature will be a list of needed commissary stores. It must be seen that all the men are employed—the morning is the time for work. The temperatures in all febrile cases will be taken and recorded—the surgeon will be sure to ask for them.

Before the surgeon's visit there will be time to enter all new cases in the register. The Index must be carefully searched, and the names not already there be entered; also the new hospital number of each case, and the last previous numbers will be noted on the Register. The age, nationality, previous service of each new addition to the Index will be ascertained. The record of each case returned to duty will be completed at once; if any point be doubtful, a memorandum for reference to the surgeon when he comes will be prepared. If the register be completed as far as practicable each day, the work at the end of the month will be greatly reduced.

Morning Visit of the Post Surgeon. — The steward precedes the surgeon, and, as he enters each ward, calls "Attention!" when each nurse and those patients who are out of bed will rise, and remain standing in a line at the foot of the beds until the officer's departure. Should much time be required in the ward, the surgeon may direct the men to sit down; then each will rise at the surgeon's approach, and remain standing until the next patient is addressed. The same direction may be given to individuals. The nurse in charge of the ward will follow the surgeon and steward from bed to bed.

The steward should verify the number of men in the ward and call attention to absentees. This is better than to have the surgeon call attention to a discrepancy between the Morning Report and the number of cases that he has seen. On a memorandum block is noted the prescribed treatment for each case and any operation done by the surgeon; if an abscess is opened, if a man complain of pain or lameness, the anatomical locality is noted; if a tooth be extracted, a record of which tooth. These seeming trifles frequently have a remote importance; and the completeness of the record will be a source of gratification to the surgeon and to the steward. Note is made of which cases are to be allowed to leave their beds, to visit the dining-room for meals, to have special diet, to be provided with crutches, etc. These memoranda will be carefully copied in the proper column, and opposite each man's name, in the blank-book described and illustrated by Table I., p. 457.

The prescribed treatment for each case will now be provided. The nurse should apply bandages, poultices, and other dressings, under the immediate supervision of the steward. Neatness, cleanliness, and efficiency must be secured. This may take more time than to do it himself, but this instruction given is like bread cast upon the waters—it will return as a diminution of labor hereafter. All unused vials are taken to the dispensary, carefully washed, and stored for future use. Corks, once used should be washed and kept in a separate drawer for use with liniments and other external applications. These little economies will prevent a shortage toward the end of the year. A mental inventory of medicines left in the ward will be taken, so that if a patient takes too much or too little, the defect may be discovered and corrected promptly. Instruction will be given the cook as to special diets.

The Daily Mail now lies on the surgeon's desk; he will indicate whatever action is to be taken upon each paper. Each communication will be stamped with the date of receipt, and such as have not already received that attention will be briefed. Each is numbered to correspond with the records. In the Letters-received Book will be noted the number, source, date, date of receipt, import, and disposition of each communication; if sent away, cross-reference will be made to the Endorsement-book; if a reply to a letter sent, make cross-reference to the Letters-sent Book, in which will be noted the number of this reply. If an important letter is not for file in the office, it is safer to copy it in full—a brief may not convey the full meaning of the writer. All letters sent must be copied in full in the proper book, and all endorsements in the Endorsement-book. The letter-press does not give an official record and can seldom be used to advantage. When bringing letters and endorsements to the surgeon for signature, it is well to also present the Record-book that he may verify and sign the retained copy at the same time, and the books are always ready for an inspector. Careful comparison will insure that all retained copies correspond exactly with the papers forwarded. This little extra work will often save misunderstanding, which ever breeds voluminous correspondence. If reports are returned for correction, a special list of such errors will be a useful supplement to the files of orders and circulars, and a safeguard against stumbling twice on the same stone. A growing list will warn the steward of a flaw in his habits.

The mail brings also general orders, circulars, letters of instruction, decisions, etc. These are compared with Army Regulations, the Epitome of Orders and Decisions, the Handbook of the Hospital Corps, or the Drill-book, whichever may be affected, and marginal references made to the new modification, giving the number, date, and source of order. An R for revoked, or an M for modified, will often save the necessity for searching the files.

First-Sergeant's Call will now summon the steward to the last of his morning duties. He goes himself to the Adjutant's Office and obtains with the Morning Reports a copy of all orders and circulars affecting the Medical Department for entry in the Order-book. The strength of the command is to be entered in the Morning Report of Sick, by the sergeant-major. The causes of any changes in the command will be ascertained, as they are required to furnish explanatory remarks.

Dinner is now ready to be served. The steward will look through the dining-room, kitchen, and wards, with an eye for defects. He will ask the seriously ill if there is anything else that they would relish; such little attentions are highly appreciated by invalids and make the days of confinement seem shorter and less irksome. The attendants, also, are cheered by his constant supervision; that his critical eye approves, is sufficient reward for what would otherwise be deemed thankless drudgery.

We have thus far considered duties that come every day with the certainty of each succeeding sun; others come periodically, at various intervals, and will sufficiently occupy the steward's afternoons.

Rations are usually drawn on the 10th, 20th, and the last day of each month. At surgeon's call a Ration Return, prepared as far as practicable the preceding evening, is completed. The columns for number of men and number of rations are filled in; the spaces for quantity of each component are left blank. It is specified for whom the rations are drawn: for so many sick in hospital, so many privates of the Hospital Corps; when a return is made for individuals, they are specified

by name and rank. Entered in the column for remarks is a tabular statement of balances due to, or from, each company. If the resultant balance is in favor of, or against, the hospital, the amount is added or subtracted from number of rations. The word Add (or Deduct) will render the matter sufficiently intelligible.

This settlement with the companies is a matter for frequent dispute; and the steward will save himself much annoyance if he is careful to be always right. To verify the work, find the sum total of the sick in hospital for all the days covered by the previous return, as shown by the Morning Report; to this amount, add one ration for each man admitted to hospital after surgeon's call, and before dinner, during that period. To this amount add the present balance due companies, or deduct the present balance due hospital; and the result should equal the product of the number of men drawn for on the last return, by the number of days. When men are admitted after dinner, it is better to lose a supper and breakfast than to dispute about fractional trifles; but when a man is fed an entire day, the ration belongs to the hospital and must be insisted upon. This may seem a trifle, too; but economy in trifles is the secret of successful hospital fund management. A ration so lost but once a week will in a year amount to the subsistence of a man for fifty-two days. Further, if the steward is found careless in this matter, first sergeants may soon find valid excuses for having sick men reach the hospital too late for surgeon's call, to the inconvenience of the medical officer and decided loss to the fund. Keep a separate memorandum of these cases, as an account of them does not appear on your Morning Report. Table II. is a convenient form for this: the first column is a list of all organizations with which accounts are kept; the second column shows how many rations are drawn for men of each at the commencement of the period; a column for each day of the period shows how many men of each are fed. These numbers should be entered every evening, and, when a new return is made, the numbers in hospital that morning are entered and balances computed.

Table III. shows the dates included in a return and the total number of rations. The first column is a list of the several components of the ration; the second shows the number of each to which the hospital is entitled; the third is the number left in the subsistence department, to be paid for in cash at the end of the month; the fourth column shows the number of rations of each component that you desire to draw out; the fifth, and last, is the cook's column, and tells him the exact quantity of each article that he is to receive. He takes this paper with him when he goes for the rations, and there can be no errors of computation.

Table IV. is a convenient slip to have on your desk when you make the computations in Table III. It it well to compute quantities by two methods, as a check to possible errors; or to verify by reversing the process and reducing the determined quantities back to number of rations.

TABLE II.

Ration Memoranda.

Patients fed, May 1 to 10, 1896, inclusive.

TABLE III.

Rations drawn, May 1 to 10, 1896, inclusive. Number 140.

Components.	Rations.	Saved.	Drawn.	Bulk drawn.
Salt pork	20	4	16	12 lbs.
Bacon	24	8	16	12 lbs.
Beef, fresh	98	14	84	105 lbs.
Soft bread	120	..	120	.....
Flour	20	20	...	15 lbs.*
Beans	60	..	60	9 lbs.
Rice	44	14	30	3 lbs.
Hominy	20	..	20	2 lbs.
Coffee, green	140	40	100	10 lbs.
Sugar	140	..	140	21 lbs.
Soap	140	15	125	5 lbs.
Salt	140	15	125	5 lbs.
Pepper	140	40	100	¼ lb.
Vinegar	140	15	125	1⅛ gal.
Potatoes	112	.	112	112 lbs.
Onions	28		28	28 lbs.

* Two ounces of flour is drawn for each ration of soft bread.

TABLE IV.

Ration of U. S. Soldier.

Components.	Rations to bulk.	Bulk to rations.	Quantity, 100 rations.
Salt pork	Deduct ¼ pounds	Add ⅓	75 lbs.
Bacon	Deduct ¼	Add ⅓	75 lbs.
Canned beef	Deduct ¼	Add ⅓	75 lbs.
Fresh beef	Add ¼	Deduct ⅕	125 lbs.
Salt beef	Multiply by 11 and divide by 8.	Multiply by 8 and divide by 11.	137½ lbs.
Flour	Add ⅛	Deduct ⅛	112½ lbs.
Soft bread	Add ⅛	Deduct ⅛	112½ lbs.
Hard bread	Number of rations is number lbs.	Number of lbs. is number of rations.	100 lbs.
Corn-meal	Add ¼	Deduct ⅕	125 lbs.
Beans	Add ⅓ and divide by 10.	Multiply by 10 and deduct ⅓.	15 lbs.
Peas	Add ⅓ and divide by 10.	Multiply by 10 and deduct ⅓.	15 lbs.
Rice	Divide by 10	Multiply by 10	10 lbs.
Hominy	Divide by 10	Multiply by 10	10 lbs.
Coffee, green	Divide by 10	Multiply by 10	10 lbs.
Coffee, roasted	Multiply by 8 and divide by 100.	Annex 00 and divide by 8.	8 lbs.
Tea	Multiply by 2 and divide by 100.	Annex 00 and divide by 2.	2 lbs.
Sugar	Add ⅛ and divide by 10.	Multiply by 10 and deduct ⅛.	15 lbs.
Vinegar	Divide by 100, gallons.	Multiply by 100	1 gal.
Soap	Multiply by 4 and divide by 100.	Annex 00 and divide by 4.	4 lbs.
Salt	Multiply by 4 and divide by 100.	Annex 00 and divide by 4.	4 lbs.
Pepper	Divide by 400	Multiply by 400	¼ lb.
Potatoes	The same number	The same number	100 lbs.
Onions	The same number	The same number	100 lbs.
Candles	Add ⅛ and divide by 100.	Multiply by 100 and deduct ⅛.	1½ lb.
Yeast powder	Multiply by 4 and divide by 100.	Multiply by 100 and divide by 4.	4 lbs.

Decimal Rule.—Rations to bulk: Multiply by quantity in one hundred rations and point off two decimal places. Bulk to rations: Annex two ciphers and divide by quantity in one hundred rations. Reduce common fractions to decimals and annex additional ciphers to dividend for each decimal place in divisor.

The Quantities to be Saved vary with the character of the cases under treatment, and can only be determined by judgment and experience. A number of cases on low diet, and severe febrile cases subsisting chiefly on hospital stores, will allow a saving of some rations of meat and flour. The allowance of sugar is always required for use. Beans, being a nitrogenous food and supplementing the meat ration, for use are preferable to rice—a pure starch; but, as the money value is greater, it is better to save rice than beans. You will draw enough rice to give variety and supply convalescents from severe illness. Generally, one-third of the coffee may be advantageously saved, and the money value invested in other luxuries. Tea can seldom be drawn or saved profitably. The quantities drawn should be, if possible, an even measure or weight, and all fractions computed in the savings; when the commissary-sergeant guesses at a fractional measure or weight, the hospital is sure to lose.

Where the fund is small, enough must be saved on each return to cover all purchases that it may be desirable to make during the ten days, to avoid indebtedness; otherwise, it is more convenient to draw all but fractional quantities on the first two returns of the month and make up the savings on the last. There should be a balance left over in the kitchen; if the cook thinks his quantities are for an exact ten days, he will not estimate the amounts required for each day, but will use one-tenth of the whole—with consequent waste.

Purchases from the Hospital Fund, under the supervision of the post-surgeon, will always be the steward's especial province—a duty that he can never delegate to an assistant. This is a subject of very complex bearings, about which a volume might be written. To expend the money received for uncousumed rations would be simple enough: to do so judiciously, to the best advantage, will deserve his life-long study and prove a subject about which he can learn something until the last day of his service. He must constantly consider the nutritive, the economic, and the commercial values of the various articles of diet, the habits and tastes of the men, the skill of the cook in the various methods of preparation, and the class of diseases under his charge.

The aim of any system of dietary is to supply in due proportion all the elements required by the human body under the conditions in which it is placed. The bulk consumed will be such as to secure a sufficiency of proportionately deficient elements. The sense of satiety comes with such a distention of the stomach as experience with the accustomed diet has shown to be necessary for that purpose. The surest and most economical method of securing all elements in due proportion is to give variety to the daily fare. The cook who provides but one dish for each meal will prove expensive and unsatisfactory. The Esquimau consumes an astonishing amount of blubber, not so much because the climate requires a large proportion of fat—of which he consumes a great excess—as because such a quantity is necessary to secure a sufficiency of elements proportionately deficient in such a diet. This lack of variety also explains the voracity of the American Indian. On our Mexican border, where the costume favors such observations, the protuberant abdomens of the little Mexicans is a subject for frequent remark; to a physiologist this tells a tale of a long-continued monotonous diet of jerked beef and tortillas.

The farmer's boy reared on a diet of salted meats, robbed of many of their nutritive elements by the brine, when he enters the army, astonishes by his gluttony the old soldiers accustomed to a diet of fresh meat, and grumbles at the insufficiency of the soldier's ration. It is well to give such recruits a proper sense of fulness by a liberal supply of cheap and bulky articles of low nutritive value, as potatoes, cabbage, fruit, etc. To freely supply such men with a concentrated diet is to make them ill. The excessive percentage of sickness among recruits is largely due to cloying the system with an excess of nutritive elements; and confinement to bed on light diet is curative of many ills. With such cases it is important to know that additional food is not smuggled into the ward byi njudicious friends. In diet as in other things, a few months will convert the recruit into a soldier. A captain told me of a man whose appetite excited general remark. A non-commissioned officer was detailed to observe and record the amounts consumed, with a view to making application for the man's discharge from the service. He ate forty ounces of bread daily, and other things in proportion, for a fortnight; then his appetite rapidly diminished until he ate no more than other men. The captain thought that the man discovered that he was being watched, or that a sense of incongruity aroused his self-denial; but a more probable explanation is, that his system became cloyed by excess, and that his stomach finally adjusted itself to the unaccustomed richness of a soldier's fare.

Purchases should be made with a view to present variety, and to effecting a saving of some component of the ration from which future purchases can be made.

Fresh Pork, at the contract price of beef, will give pleasing variety and prove an economy during the cold season, when it can be kept. The cook will render the lard and save all unconsumed grease for culinary use, so saving an otherwise necessary purchase from the commissary.

Turkeys, Chickens, and Oysters, bought for invalids or holiday dinners, often prove surprisingly economical investments. Much depends upon the market price, but the small percentage of bone, as compared with beef, must also be cousidered.

Eggs have a high nutritive value, but lack the bulk required to give a sense of satiety. Served in unlimited quantity, they seldom prove an economy. On toast, or in cake or custard, an egg will be highly relished, give pleasing variety, and allow of a certain saving of meat. But bulky food must be served at the same meal.

Milk is an ideal food, containing all the elements necessary to maintain life. An animal food, it will take the place of a part of the meat ration. When supplied freely it should be served with bread, oat- or corn-meal mush, or other coarse diluent, as its undigested residue is so small that troublesome constipation will result from long-continued use by itself. Except as a flavoring for coffee, occasional use in puddings and custards, and as special diet for invalids, the hospital fund will seldom justify the purchase of milk. Aside from adulterations, its market price generally exceeds its nutritive and economic value; the milkman must be paid for his life of drudgery, for the use of his horse, cart, and bell. Where there is sufficient fund to pay for her, a good cow is probably the best investment that can be made from the hospital fund. The attendant who does the outside policing will not feel the additional work; the kitchen waste will supply a large part of her food; and an unstinted supply of milk will reduce the demand for various components of the ration and cut off an otherwise necessary monthly milk bill of five or ten dollars. Where more than twenty men are fed, a second cow will be advantageous.

Butter is a judicious investment if the price is not more than three or four times that of beef. Where fresh beef is the chief part of the meat ration consumed, there is apt to be a deficiency of animal fats, and butter is a useful and highly relished addition to the soldier's fare. There is less demand for it when fresh pork and gravies are served. It is not essential, and may be omitted when a reduction of expenditure is required. Care is necessary to secure it of constantly good quality.

Cheese is a food whose nutritive value constantly exceeds its market price. A concentrated food, its economic value is impaired by its deficient bulk. If served in unlimited quantity, the excess taken to produce accustomed distention of the stomach will speedily induce digestive derangements; but a daily allowance of two or three ounces for each man will prove a useful and grateful substitute for a part of the meat ration.

Fresh Fish, when attainable, make a useful variation in the bill of fare; but money paid for transportation does not help to nourish the soldier. Salted fish are of but little use except to satisfy the longings of a petulant invalid. When fish are served at all, let it be on Fridays, to show a proper deference to the religious feeling of some of the men.

Oatmeal, Cracked Wheat, and Hominy may often be advantageously substituted for a part of the flour ration. Vigilance is required to insure that they are always thoroughly cooked.

Sirup is always a cheap and useful luxury, relished by all.

Fruits are a valuable addition to the dietary, where we pay for fruit only, and not for long transportation. At many stations, desiccated fruits and canned tomatoes are the only resource. The vegetable acids fill a useful rôle in the processes of assimilation; and their only representative in the soldier's ration is vinegar, of which the allowance, though small, is rarely consumed. Beans and boiled pork are the only components of the ration that are rendered more palatable by the addition of vine-

gar ; hence, as incentives to an increased consumption of a vegetable acid, such products from the garden as pickled onions, cabbage, and tomatoes assume in the dietary an importance far in excess of their trifling nutritive elements. The commissary substitutes are beyond our means, as we can ill afford to pay for glass, long transportation, and insurance to middlemen against breakage. Oranges, lemons, grapes, and the more expensive canned fruits can be served only as special diet for invalids.

Salt and Pepper, as condiments, require passing notice. Salt, being a constituent of every fluid and tissue of the body, except the dental enamel, is a very important nutritive element ; but it is naturally present in every article of food, and in drinking-water. Its culinary use to render food more palatable, is generally in excess of the requirements of the system ; and in such excess it must be considered as a condiment. The failing of nearly all cooks is to use these articles in excessive quantity. Salt and pepper must always be within reach, that each man may flavor his food to his taste ; and the cook should be instructed to limit his seasoning to a minimum requirement. We would not compel a horse to take more salt than he wants by mixing it with his oats ; and man is deserving of equal consideration.

These are a few general landmarks given to guide the steward in hospital fund management. He will add to and modify them as experience dictates. Curious fluctuations, beyond explanation, will be observed ; in some months there will be large savings ; in others, under apparently similar conditions, it will be difficult to avoid a deficiency. To provide for these refractory variations is an important function of a hospital fund. It is well to keep the expenditures well below the savings, accumulating a few dollars each month, until there is a constant balance on hand proportionate to the size of the post. Thirty or forty dollars is enough at a station of one or two companies ; a hundred and fifty or two hundred is not too large an amount for a regimental post. Until there has been accumulated such a fund, there will be constant trouble "to make both ends meet," and the hospital mess will be of the plainest. With a suitable reserve we can indulge in various luxuries ; a shortage of ten or fifteen dollars in one month, which may readily be made up in the next, will be of little importance. Expenditure for games, reading matter, etc., will then be proper ; but, to give variety to the soldier's fare, is always the main object of a hospital fund.

With constant attention the steward will improve his methods from year to year ; the ultimate possibilities of hospital fund management have never yet been attained. The steward of a lake steamer, whose table was laden with every luxury of the season, told me that the average daily cost to feed a passenger was nineteen cents.

Near the end of the month every item of receipts and expenditures is entered in the record of the hospital fund, and in an exact copy to be sent away. A careful steward will compare the two, item by item, and go over the computations again to know that they are correct, before he presents them for the surgeon's signature. We cannot rely upon the commissary sergeant's accuracy ; all are fallible, and he has much to do.

Fuel, Mineral Oil, Forage, etc., are obtained by requisition, sent to the adjutant's office on the last day of each month. The authorized number of fires and lights are required for, care being taken to ask for enough ; the quartermaster takes up unconsumed balances ; but should a change of weather necessitate more fires than have been estimated for, he cannot supply the fuel. The supply of these things is liberal, and it is our duty to guard against waste or misappropriation. We can compute the aggregate capacity of all lamps in use, they are filled but once a day, and a lamp rarely fails for lack of oil, and oil must not be used for kindling fires. When the daily expenditure of oil approaches the total capacity of the lamps, it is time for increased vigilance. Man is largely a creature of circumstance, and it is well to let all feel that the steward's supervision extends over everything about the hospital.

Where a large civilian population is unprovided with the means of obtaining fuel, the wood and coal bins will be subject to nocturnal visits. Gates will be left open, scattered coal will derange the policing, and in many other ways these visits are objectionable. All that can be done is to render access to the fuel as difficult as possible, with a hope that such visitors may go elsewhere, like electricity, choosing the course of least resistance.

The Monthly Report of Sick and Wounded is a record of completed cases, arranged to accord with the hospital numbers. As each case is returned to duty, or otherwise disposed of, its record in the register is completed, but the monthly report cannot be begun before the end of the month, unless all back numbers are complete. There is no trouble with cases admitted during the month, but without great care, some of the cases scattered through the records of preceding months will be skipped, and the sequence of the hospital numbers will be broken. To avoid this, at the end of each month prepare a memorandum slip of all remaining cases ; verify this with the numerical summary, and check off each number as the cases are completed. When all are checked off, the monthly report can be begun, and the record be brought down to the oldest remaining case, which will sometimes greatly reduce the work at the end of the month.

Changes in the command will be noted, and the required data concerning births, marriages, and deaths, be obtained as they occur. A careful record of the data given will relieve the steward from responsibility for future trouble about personal identification, legitimacy, and other points that may be raised by the Bureau of Pensions.

Muster- and Pay-rolls have sufficiently explicit printed directions. As is true of other papers, accuracy, legibility, and completeness are qualities which are essential to them. They cannot be prepared long beforehand, as changes may occur at the last moment. At the end of each alternate month, when no muster-roll is sent to the adjutant-general, a report of strength and changes in the command must be forwarded.

The Report of Examination of Recruits can be kept up with the record, of which it is an exact copy, and need not consume time at the end of the month. That a recruit is not "accepted" when he has passed the medical examination, but must be actually sworn into the service, is to be remembered.

The Report of Personnel, the Sanitary Report, and *the Personal Reports of Medical Officers*, complete the list of monthly papers.

Returns of Ordnance Property, of Quartermaster's Stores, and of Clothing and Equipage are made quarterly. In military departments where an extra copy is required by department orders, a memorandum of such orders should be found in the hospital steward's digest of current orders and decisions.

The Annual Return of Medical and Hospital Property is made at the close of each calendar year, and whenever a medical officer is relieved from responsibility. When this return has been examined and found correct in the office of the Surgeon-General, notice is sent to the officer interested. The receipt of this notification marks the time to begin one copy of a new Return. The quantities "on hand to be accounted for" can now be entered on the first line. Should the receipt of new articles during the preceding year have deranged the alphabetical arrangement—or classification—now is the time to make adjustment. Blank columns are left after each class for such new articles as may be received during the year. When invoices are received the amounts are entered at once in the proper columns ; the same is done under expenditures for property sent away, inspected and condemned, or otherwise disposed of. We shall thus have at hand a complete statement of accountability, and be ready at all times to prepare correct invoices. Should a change of station or other cause necessitate a transfer of property accountability, an intelligent inventory, general or partial, can also be taken with accurate knowledge of what

ought to be found. That an article will be speedily missed, is a safeguard against loss.

Care of Property.—Upon taking charge of a hospital the steward's first duty is to ascertain what there is in it to be accounted for, and the location and condition of each article. Before beginning his inventory he must remember that there are eight classes of property to be considered, and he should obtain from his predecessor the retained returns and subsequent invoices, showing what must be found.

1st. The post quartermaster issues stoves, pipe, lamps, bunks, and many other articles upon a memorandum receipt, of which the steward should possess a copy. The steward must go over this property carefully, that he may recognize the various articles and not confuse them with property of some other class—so counting the same article twice. For example, the galvanized iron bucket is stamped U. S., and a similar bucket, stamped M. D., is carried on the return of medical and hospital property. If we find a surplus of the one, we are likely to find the others deficient; used for kitchen waste, fatigue parties exchange them, and the shortage is of medical and hospital buckets. Once wrong, it is very difficult to straighten the matter.

2d. There is the return of quartermaster's stores—ambulances, harness, water-kegs, and other equipments, which it is very important to see in their proper places.

3d. There is a return of clothing and equipage, of which all articles of bedding should be found, separate and distinct from similar articles of medical and hospital property.

4th. The return of ordnance property.

5th. Certain books may be carried on the muster-rolls and also on the return of medical and hospital property, so that the steward must find duplicate copies.

6th. The return of durable property purchased with the hospital fund.

7th. The annual return of medical and hospital property.

8th. The return of record books. Of these the older ones have become ancient history and are liable to be stored in out-of-the-way places; the assistance of his predecessor may be required to find them, and he may save himself hours of fruitless search if he finds them now.

In taking the inventory it must be seen that every article is on hand; and any excess of articles not expendable carefully noted with the amount. Such excess is always a subject for suspicion, and may prove as troublesome as a shortage; it implies a blunder somewhere whose shade may arise again quite unexpectedly. An officer, in taking an inventory, found a surplus of several sets of tent-poles. Being a careful man, he took them up on his next return, "from source unknown." Several years after, he received official notice that a lieutenant claimed to have issued him this number of tents and poles, and, through error, to have omitted the poles from his invoices. The officer invited attention to his return for such a quarter of such a year on which these poles had been taken up and duly accounted for. Had he neglected this unaccountable surplus, the poles would have been worn out and thrown away, and he would now have found himself accountable for property that he no longer possessed.

It is the duty of the steward to know, at all times, where every article is to be found. To do this his memory must be aided by a systematic arrangement. Of the articles in actual use, lists must be made for each division of the hospital—office, library, dispensary, wards, kitchen, and dining-room. The attendant in charge of each must be furnished with a duplicate list, and warned that he must report promptly any missing articles, with the circumstances of their disappearance, to avoid responsibility for the loss.

Each soldier is charged with his accoutrements, which are verified at inspections and must be turned in before he receives his discharge.

Of property not in use, each class should be stored by itself; and the articles, as far as practicable, arranged in the order in which they are borne on the returns. This will greatly facilitate the taking of inventories, and prevent loss of time in searching for any article when wanted.

There will be noted in a memorandum-book the transfer of articles from one place to another. From this can be determined the rate of expenditure of medicines and stores from the dispensary and kitchen; and can be traced unreturned appliances used in the treatment of cases outside the hospital.

Attendants can be held responsible for the condition of articles in actual use under their charge; but the property kept in the store-rooms requires the steward's constant and particular attention. Blankets and other woollen articles must be secured from moths by tarred paper, marine lint, or other device. Hospital stores must be guarded from the inroads of mice. Wooden articles, buckets, wash-tubs, etc., will become rickety in dry store-rooms and require to have hoops tightened, or to be soaked in water. Water may be left in the kegs during the summer, but they must be carefully emptied before there is danger from frost. If harness is hung in a basement near steam-pipes, the leather will become hard and lose its pliability; if hung in the same basement without artificial heat, dampness may provoke the growth of mould. If the pack-saddle is not secured in tarred paper, the woollen pad must be protected from moths by frequent beating and exposure to air and sunlight. Garden tools must be carefully housed, and, after their season of use has passed, cleaned, oiled, and secured in a suitable store-room. The empty barrels will be needed again for sauer-kraut and pickles, and must not be allowed to fall down for lack of attention. In careful housekeeping eternal vigilance is a useful watchword.

The Ward is, to the hospital, the vital centre, the source of being; all other parts are but accessories to its welfare; and we may well study the conditions that promote its usefulness.

Upon the occurrence of sickness and death the savage moves his camp. This blind following of superstitious ignorance, or traditional experience, approximates in results the most advanced sanitary philosophy. But in the ward there can be no change of camp; suppurating wounds, gangrenous frost-bites, foul ulcers, erysipelas, consumption, pneumonia, infectious fevers, etc., form a continuous pathological chain of which some links are ever present; with modern knowledge of disease-producing germs, the illustrated annals of a ward would appal the stoutest-hearted patient, and attendants might indeed shrink from the performance of their duties. On the contrary, experience teaches that there is less danger in the ward of an army hospital than in the ordinary walks of life. A man with small-pox lands on a wharf and proceeds up a street, stopping here for drink, there for food, and again for rest; in a fortnight, a trail of yellow flags will mark his line of march, and those who came in contact with him on the street will furnish other victims. A man with high fever is admitted to a ward full of patients. On the third or fourth day a small-pox eruption appears, and he is then carried, with his bed and belongings, to an isolation ward or tent. Of the patients and attendants in that ward the probability is that not one will have small-pox. If one man does contract the disease, it will be the attendant who came in contact with the patient upon admission and handled his clothes. The same is true of other infectious diseases. When typhoid fever appears in a house, several of the inmates contract the disease; in a ward, the man with a broken leg is in no danger from the case of typhoid fever in an adjacent bed. Rarely will a patient contract another disease while confined to a bed in the ward. Convalescents, who are permitted to walk about, are in greater danger from the other inmates, but even they are more likely to have contracted the new complaint during surreptitious absence. When apparent exceptions occur, careful inquiry will generally elicit the fact that the germ of the second disease was received before admission; a man with two diseases may only complain of the one that causes him the greater inconvenience.

We must not depend upon fortunate accidents; we must study the conditions that give the ward its freedom from contagion—its salubrity—that we may not interrupt them by injudicious interference; that we may approximate them in other buildings, used temporarily as hospitals; that we may maintain the efficiency of the hospital corps by guarding its members, as far as possible, from contagion.

A hospital ward is a parallelogram of floor space 25 feet wide, whose length is determined by the number of beds that it is to contain. The beds are placed with the heads to the lateral walls. There is a window in each alternate interval between them. Commencing in a corner, we have a bed, a window, a bed, a space. Allowing 4 feet for each bed and each interval, 16 feet is the unit of length providing for two beds on a side. This unit may be repeated as often as desired; generally, for economy and convenience of administration, it is repeated three times, and, as the unit terminates with a space, an additional 4 feet is added for a seventh bed, and the last space provided with a window on one side, and, on the other, a door opening into the lavatory. This gives for each bed nearly 93 feet of floor-space and more than 1,000 cubic feet of air-space, with a ceiling 12 feet from the floor. With ordinary percentages of disease and accident this is satisfactory; in epidemics of infectious disease, without extreme care of the ventilation, such a ward will be overcrowded. Under all circumstances the corner beds are undesirable and should be assigned to sprains, bruises, and other slight ailments.

The ventilation of a ward should be entirely independent of doors and windows. In the centre of the ceiling an open shaft of 2½ feet in width, and 15 feet in length, should extend to a ridge ventilator. Twelve feet from each end of the ward, an opening of one square foot should be cut in the centre line of the floor, to communicate with an air-shaft extending across the building and opening at both ends outside. These shafts should have a sectional area of 16 by 16 inches, as the ends must be somewhat obstructed by wire netting to exclude small animals that might hide in the shaft to await death. Care must be exercised that the outer openings be not obstructed by snow or rubbish, and that the ground in their vicinity be kept scrupulously clean. No slop-barrels, cesspools, or sewer openings can be tolerated in their neighborhood. In malarial regions the areas near fresh-air inlets should be covered by an unbroken turf. Provision may be made for closing the windward end of these air-shafts, as rapidly moving air carries dust, bad odors, filth, and morbific germs for great distances; and it is safer and more pleasant to get the fresh air from the lee side of the building. This arrangement for closing the ends of the air-shaft is preferable to a closing flue in the floor opening which cuts off the supply of fresh air altogether. If the ward be warmed by stoves, they will be placed over the fresh-air inlets, and the pipes be carried out through the centre of the ventilating shaft. One stove cannot be so located as to satisfactorily warm a ward 52 feet long; the required heat will render adjacent beds untenable, while remote parts of the room are still cold; further, only the radiant heat can be utilized from a stove placed in the centre of the room, as air warmed by contact will pass directly up the ventilating shaft. The stoves and pipe should present a heating surface sufficient to warm the room in all seasons without the fires being forced. No approach to redness should ever be tolerated in a ward stove.

We will now consider the practical isolation of each patient in the ward. Disease germs may be communicated by contact, by food or drink contaminated by utensils used in common, and by floating particles of dust or moisture in the atmosphere drawn into the air-passages by inspiration.

Direct contact between patients need never occur. An attendant's duties expose him to some danger which can be minimized by trifling precautions. The clothing of each new patient should be removed from the ward at once, aired and dried if necessary, and then placed in a tight locker. If this is done in all cases, the unrecognized infective case will seldom cause trouble. Each patient has his own bedside table, medicine glass, spoon, etc.; his food is brought to him separately, and the soiled dishes are disinfected by boiling water in the kitchen. This obviates sources of infection more common than is generally supposed. I would not eat or drink in a house containing small-pox or diphtheria, and yet I attend such cases without anxiety. A cup of tea flavored with kerosene, and other similar observations, lead me to doubt the effective cleanliness of apparently well-regulated households, and suggest how germs may travel beyond the hangings saturated with antiseptics.

A drunken man besmears the sheets, or a patient uses a close stool or bed-pan in the ward without inconveniencing his neighbors. There is no need for the burnt sugar whose odor is so unpleasantly suggestive of poor ventilation in the sick-room of many a mansion. The reason is, that the heads of the patients are next the outside walls, and that all air-currents are toward the centre of the room, and upward toward the ventilating shaft. The man with the broken leg will wish to smoke in bed. Watch the course of the curling wreaths as they disappear; by them the air-currents are rendered visible. No stagnant strata lie above his head; no smoke crosses the interval to the next bed until it has risen high above it. If some smoke drifts against a cold window-pane, it grows heavy and falls directly to the floor—showing why it is not well to place a patient's head opposite a window, for all foul air takes the same course. This also illustrates the advantages in winter of double sash with a dead-air space between, and teaches us to provide for ventilation elsewhere. You will also see why longitudinal draughts are injurious, deranging the normal air-currents and carrying foul air across the beds. In summer, open opposite windows that the stream of air may pass between the beds and tend to draw impure air from the beds toward its centre.

A ray of sunlight through a shutter illuminates floating particles in the air; these are the omnipresent dust. The sailor in mid-ocean sweeps his deck and wonders whence it comes. There is danger in it—morbific germs may ride upon those little particles. We cannot exclude it from the ward; we can only change our dust as we do our air, by ventilation—judging that from the outside world to be less dangerous. The humble piece of soap, in the society of the rose, partook somewhat of its perfume; so dust, allowed a long sojourn in a ward, will acquire morbific qualities. Daily sweeping and dusting is a wise sanitary precaution. The direction of normal air-currents will be the guide for the sweeper—everything toward the centre is an invariable rule. The proceeds should be gathered on a dust-pan and consigned to the fire. To attempt to sweep through an open doorway, with the possibility that a gust of wind may scatter the dust over the beds, should be a punishable offence. There being but little travel through a ward, and all accidental litter being removed at once, but little dust will be raised at each sweeping; but a half-hour later, every projecting shelf, window-sill, casing, and cornice, together with the furniture of the room, must be gone over with a moist cloth.

The bed-linen is changed as soon as soiled, and at the departure of each patient; if there be a suspicion of contagion, it should be soaked in an antiseptic solution and dried before being sent to the matron. In all infectious cases the mattress, pillows, and blankets must be thoroughly fumigated; the surgeon will decide if destruction be necessary. Whenever a bed is vacant, the bedding should be exposed to air and sunshine. This will avoid the necessity for a complete change of outfit periodically. At times of little sickness patients may be so consolidated as to leave a ward vacant, which can then be fumigated and put in perfect condition. If such a ward can be allowed to lie fallow for a few days, this will make a desirable break in its pathological chain.

Surgical Operations bring important duties to the steward. The surgeon will select his instruments and give directions for antiseptics and dressings for each case; but the steward should be familiar with the general prin-

ciples underlying aseptic surgery, for his ignorance or inattention may nullify the most consummate surgical skill. To take antiseptic gauze from its hermetically sealed package, unroll it on a dusty counter, cut it with rusty old shears hanging in the dispensary for general use, and turn it over to the unwashed hands of a nurse for consignment to the first bedside table that he comes to, is a combination of errors too frequently excelled.

After every operation, however trivial, the instruments must be washed, dried, placed in a covered tray, and, after twenty-four hours, rubbed carefully with chamois leather; then, and not till then, can they be safely returned to the cases. The seams of a leather pocket-case may retain the germs of erysipelas while the ward is refloored, re-ceiled, and re-painted—in vain.

The Dying and the Dead will also claim the steward's consideration. The greatest tact and judgment must be used with the dangerously ill. We must not destroy the last chance of recovery by depriving the patient of hope; but the steward can lead him to think of the general uncertainty of life, and to confide to him the names and addresses of friends whom he would wish to have informed, should his case prove unfortunate. We must note his expressed wishes and parting messages carefully—the words may have a meaning for friends which we cannot understand. Should the patient ask to see a friend or a clergyman, a messenger must be provided promptly. These wishes may have an importance that you cannot appreciate. You cannot put yourself in his place, and the bitterness of helpless disappointment may be more cruel than his physical sufferings. There is a sharp distinction between the friends that the patient asks to see, and those friends who ask to see the patient; the latter may well be referred to the surgeon in charge.

Upon the occurrence of death, carefully, tenderly, reverently, but promptly, let the body be removed to the dead-room. The steward need not assume the solemn airs of a professional undertaker; but, if he considers the grief, the hushed awe, possibly the terror, of the other patients, his procedure will be marked by due decorum. The effects of the deceased will be collected and stored for safe delivery to his company commander. The post surgeon will be notified immediately, and a messenger sent to the first sergeant of the company to which the deceased belonged. The blank forms in the register of deaths and interments will be prepared for signature. There can be obtained through his first sergeant such required data as are not already at hand. After such an examination of the body as the surgeon may desire to make, it will be prepared for burial. After such preparation an attendant will await the visits of all who may desire to view the remains. We cannot exclude the idly curious, for the ties of a common humanity extend beyond our ken. We may not appreciate the importance of a parting caress, a kiss, a little prayer; but we must respect these as some of the mysteries of life.

Post-mortem Examinations.—The steward must know that all instruments are clean; must provide a bottle of olive-oil, buckets, sponges, etc.; must have the needles threaded beforehand, and see that their points are sharp. We cannot have the entire detachment present, but by rotation we can gradually disseminate some knowledge of human anatomy throughout the corps. Some of our men will turn faint and sick; we will send such into the fresh air and encourage them to try again. It is a matter of education, and preparation here will render them useful in operations on the living body. At the end of the examination, it will be the steward's duty to replace the various organs and close up the incisions. Let him aim at neatness and dexterity in the use of the needle, and accuracy and efficiency in the adjustment of parts. These accomplishments may be of use in repairing rents in living flesh. When all is done, clean all the instruments as carefully—more carefully than you do those after a surgical operation. There is something in the dead human body which causes a fatal poisoning, if, even in the smallest quantity, it is inoculated into that of the living. The slightest crack or abrasion of the skin may receive and absorb this fatal by-product of mortality. Before beginning a post-mortem examination the hands are protected by saturating the pores of the skin with oil, which can be saponified and washed away at its close, bearing away with it all other foreign matter. All bodies are not equally dangerous; those are more so in which the processes of putrefaction have begun. Erysipelas, gangrene, and other diseases in which putrefactive changes, in effusions or tissues, may begin before death, have long been known to furnish the most dangerous bodies. In a perfectly fresh cadaver there is little or no danger. Cannibals, with all their experience, seem to have remained ignorant of this peculiar quality in dead human bodies. The putrefying corpse of one enemy would have poisoned the arrows of a tribe, and yet, among the arrow poisons, this one seems to have been overlooked. Bearing in mind that this poison is a product of putrefaction, you will know that there is but little danger from a scratch received in an examination made soon after death; but you will understand that if you leave in the indentations of a knife handle, in the joint of the blade, or in the eye of a needle, particles of human flesh or oil, to putrefy in the cases, those instruments will be very dangerous when used again. If you are careful to clean your instruments immediately after use, I believe that those frightful cases of blood-poisoning will forever remain things that we read about but never see. Buckets, large sponges, in fact everything used in the post-mortem room must be carefully cleaned and put away for future use, care being taken to so plainly label them that neither you nor your successors may ever unwittingly use them for other purposes.

The Hospital Steward's Assistants.—This article is written to little purpose if its perusal does not convince all of the importance of having capable, willing men to assist the steward in the hospital work. He must appreciate the advantages of thoroughly understanding the members of the hospital corps; of knowing their capabilities and their defects; and of seeking the best methods for their training and management. It is the poor workman who grumbles at his tools—the best of steel has flaws; with even poor tools much useful work is wrought by skilful hands. Inferior tools require a careful consideration of their defects, and more constant care to keep them in serviceable condition. The study of defects is not a pleasant occupation; to render it an improving one, it must be pursued with a philosophic spirit. We unravel the intricacies of foul ulcers, of loathsome diseases, that we may the more intelligently apply remedial measures, and we find a sweetness in success to soften the harshness, to assuage the bitterness of our preliminary studies.

Of twelve carefully chosen apostles, one betrayed his Master, one denied Him, and one converted "Doubting Thomas" into a proverb. With every precaution, we cannot hope to improve that percentage among the members of the hospital corps. The men must be young, must have served a year in a company, and must voluntarily ask for transfer. Their pay is now greater, but their duties, if not so severe, are more continuous and irksome, their chances for advancement are but little better than they were in the line. To study the motive for this transfer is to gain an important insight into their character. A little more than a year ago the young man was dissatisfied with his prospects and surroundings in civil life; seeking novelty, he enlisted; after a year in the company he feels that his world still lacks in brightness; fancies that the Vale of Perpetual Content is just over the next divide, and he is transferred to the hospital corps. It is not surprising that such men become restless and discontented. This longing for change will pursue them wherever they go. No other class of men in the army will furnish an equal percentage of applications—for change of station to go anywhere—for transfer back to the line—for discharge. To a student of humanity there is a pathos in these appeals.

There is much in their duties to aggravate this spirit of unrest. In a detachment of eight men, two in the kitchen will begin their duties long before Reveille, and the preparation of three daily meals, with the necessary

dish-washing and cleaning-up, will keep them engaged until Retreat; two [one for each] must be constantly present, day and night, in the wards; one must attend to the office, dispensary, halls, and dormitory, and be ready to act as messenger if required; one attends to the outside police, keeps the ambulances and harness in order, milks the cow, and makes the garden. Six of our eight men are constantly employed; week days and Sundays the hospital work goes on. Change our men about as we will, the tours of duty are long, the intervals of relaxation, of freedom, are brief. Then this freedom is not absolute; the steward must know at all times where the men can be found. Accidents and emergencies are our especial province; and we must be prepared to give immediate assistance.

There is another restraint more irksome and continuous. The hospital is a place of sickness and suffering; patients must not be disturbed by noise. There can be no unseemly laughter, no merry jests, no rough and boisterous play, to smooth the sharp angles of life. No barrack-room ballad can originate or be repeated in the dormitory of an army hospital—the only day-room for the men off duty. The air of solemn decorum that hangs about the building is not conducive to cheerful gayety among the men.

This picture is not drawn to discourage. If the shadows are tinted too deeply, it is to more certainly fix the attention; if the obstacles are drawn in too rugged an outline, it is that the steward may so form his estimates as to surmount them the more certainly. The hospital corps is a still recent organization. Difficulties will continue to be remedied by legislation and orders as the conditions are recognized, and the means of correction fixed upon. A discussion now of many of them would necessarily be ephemeral; but certain general principles underlie all and will be true through all variations. These are worth careful consideration.

First in importance is the fact that the poorest man in the detachment is better for our purposes than the most promising recruit that comes to the post. There is something in that year of military discipline and training that improves the man; we must continue the good work. If the man does not go forward, he will slide backward; we must exact a continuance of those habits of order, of regularity, of prompt obedience. The polish of a shoe, the brightness of a button, have a direct bearing upon the welfare of the sick. Teach your men to be systematic—even in their vices; for regulation is a species of restraint, a step in the right direction. The steward's example is worth more than his precept. If he walks in the straight path, his men will follow him by instinct and without complaint; if he makes them his accomplices in trifling peccadilloes, he will lose a standing that he may never regain. Let the men be taught to regard regulations as they do the processes of Nature—which rains alike upon the just and the unjust. The rigid letter of the law does not abrogate the necessity for judgment and discretion. When a man returns from pass drunk and disorderly, consider that drunkenness, in itself, is a failing and not a crime; consider that the restoration of this man to the duties which others are now performing is our main object. Order him to his bed in the dormitory; when he has slept off his inebriation, he will be as useful as ever. Do not waste words in argument or reproof. If the man awakes in the guard-house, let him understand that this humiliation is not because of his drunkenness, but because he did not retain sufficient sense to comply with an order that was intended to shield him from trouble. Exclude all personality from this exercise of your authority. Aim to do these things as impassively as you wind the clock. In the maintenance of discipline, "In essentials, unity, in non-essentials, liberty, in all things charity," is a motto that we may well borrow from the Church.

For privates of the hospital corps much can be done to lighten the labor, to lengthen the intervals for recreation. The acting hospital steward has charge of the wards and does the dispensary work. After the morning work is done, he has little to do except to be on hand to put up occasional prescriptions. He will try to while away this leisure time by reading, and possibly by smoking. If left to himself, this sedentary life will have one of two effects: he will grow dyspeptic, morose, and irritable, or he will become apathetic and lazy. This loss of energy will be so gradual that the steward may not notice it until he is greatly annoyed by the man's inattention to details entrusted to him; and he injudiciously administers a sharp reproof, which makes him worse; he has spoiled the man, who is no longer a help, but an incubus. With an understanding of the causes, with foreknowledge of the certain results, all this is easily avoided. When the rush of the morning is over, we will encourage him to leave the hospital and seek open air diversion. A private can watch the dispensary and call the steward if a chance prescription comes in. Walking, picnics, hunting, and fishing will increase greatly the efficiency of our acting steward, and, in the end, reduce the steward's labors.

When the public health is at its best, the sick may be consolidated into one ward; for, with our small detachment, the liberation of one man is a large percentage of gain. We will try to reapportion the work so that all may experience the advantage. If our men know that we do our best to relieve them, they will continue their work more cheerfully.

With the present allotment of force, the necessity of utilizing the labor of convalescents is recognized in general orders. Every man who is able to be out of bed can make up his own bed, keep his bedside table in order, and, possibly, contribute his share toward the general police of the ward. The man whose sprained ankle permits him to be out of bed can get to the kitchen to pare potatoes and do other sedentary work. The musician whose sore lips will not permit him to blow his trumpet, is fit for any work about the hospital; if the change of avocation does not please him, he will take better care of his lips in future. The inebriate, too nervous to handle a musket, will sleep the better for handling a broom. With no critical cases in the ward, a sergeant or corporal may be charged to maintain order, and the nurse given a few hours for open air amusement.

This use of convalescents requires great discretion, and the surgeon's opinion must first be obtained in any case of possible doubt. You would not expose inflamed eyes to sunshine, wind, or dust; nor subject an inflamed arm to exercise. A convalescent who refuses to work is liable to punishment by court-martial; but there are many objections to such attempts to discipline men of other organizations; it is generally better to presume that the man is not able to work, that an error has been committed in allowing him to leave his bed so soon. If he cannot work, it is clearly right that he should go back to bed.

Men enjoy doing those things that they can do well. The steward will greatly promote the efficiency and contentment of his detachment by carefully instructing its members. Poets may be born, but cooks, nurses, gardeners, and the like must be moulded by education to fit those positions. If we spend our time seeking men exactly suited to each place, we will grow weary comparing square pegs with round holes—for us, the brightness of the world will be dimmed by many disappointments. If the steward evinces an interest in the work, his men will contract enthusiasm by contagion. If he shows his nurse the neatness, beauty, and efficiency of the reverses in a roller-bandage, the ease and comfort from its equal pressure, and the smooth skin, free from welts, upon its removal, the man will gladly peruse all works on minor surgery that may be given him, and soon become a happy adept in various bandages—spica and many-tailed.

Encourage your cook to experiment in new dishes, to accumulate a variety of recipes. Cook-books will soon be to him more charming than the latest works of fiction. While the plant is still in blossom, it is time to begin the discussion of the possibilities of a green tomato. From almanacs and cook-books he will gather a variety of recipes; encourage him to try small quantities by several of the most promising, and seek a decision of the rela-

tive merits from the gourmands among the patients and in the corps. When your hospital piecalilli attains a local celebrity, and ladies call to consult about ingredients and proportions, you will have a happy, contented, and useful cook. But something more must be obtained from him. Let him feel that passes and other favors depend upon the ability of his assistant to take his place, and we will soon have two adepts in kitchen mysteries.

If there is a hospital garden, there will be need of a gardener. The professed professional who seeks admission to the corps is of doubtful utility. He is in the army probably because he has failed in that vocation in civil life; and he will fail again, at the expense of the hospital. The old Greek was wise who charged a double fee to those disciples who had enjoyed the teaching of another master. The man raised on a farm is only a little better than the professional gardener. He left the farm in disgust; and it will be difficult to inspire him with enthusiasm for the work. If at home he dropped the corn in a depression made with his heel, he will despise a dissertation upon the advantages of sunshine and air, attained by scattering the seed in a broad hill; he will inwardly groan at the military tyranny which compels him to depart from the ways of his ancestors; and, when our back is toward him, he will revert to his original methods. We will have a much finer garden if we select a city-bred boy who has never seen a garden rake. There are many reasons for this. At the start, more personal attention must be given him. Then the charm of novelty will cheer him in his work. The proper adjustment of a clevis that the plough may glide easily to a proper width and depth of furrow, will be triumphs of his inventive genius. He will not take it as a personal affront if you show him that the wilted plant was simply hung by the neck, with roots dangling in space beneath. He will consider the success of the garden a victory for which he has reason to be proud. In times of planting and weeding, we will put convalescents in charge of the wards and turn out our whole force. The work is better done promptly; and our gardener will not become disheartened by the slowness of his achievement.

For variety, usefulness, and general charm, there is no study equal to the study of men. With these few hints to guide him at starting, may the steward pursue it with profit and delight.

Reading.—Considering the multiplicity of his duties, the steward may feel that he has no time for study; but, if he is systematic in this as in all things, he will accomplish more than the average man. When he considers that a half-hour of effective study every day is sufficient each year to learn a new language or master a new science, he will know that economy in small things is a secret of success. Because his time is limited, he will value it more highly, will use it more discreetly. The variety of learning required by his calling will suggest the importance of a systematic assortment of facts. He will make two great classes: those that he must have always with him, and those that can be found promptly when needed.

The first class must be acquired, thought over, reviewed, until mentally digested and assimilated into his personality, forming so many atoms of that sum total which the world calls common-sense. If one of these facts is used with a consciousness of the book from which he learned it, he has burdened his memory with a useless reference; he has not sufficiently mastered the thing itself. When we acquire a new fact, let us consider it as a many-sided crystal, each facet of which must exactly coincide with every other fact in our possession. We will revolve the thing in our mind, and test the accuracy of its various angles and planes. If there are apparent irregularities that we cannot adjust, we will bear the defect in mind and seek a better illumination by further reading. Let us arrange our facts neatly and compactly, and study the common lines that extend through all. We will estimate the relative importance of our various items; if we post our markers properly, all minor facts will dress into line without trouble.

The study of facts of the second class is the art of making useful memoranda. The steward cannot become a walking encyclopædia of useful knowledge. To burden his brain with useful formulæ and cosmetic recipes would be the sinful waste of an organ provided for better purposes. It is well to keep an index of things sought, in which can be entered every subject we are called upon to investigate, with references to the place or places where the information has been found. When we find the tale told better elsewhere, we enter a new reference. A scrap-book for newspaper clippings, a note-book for things that cannot be kept in the library, will often prove useful; but will grow cumbrous, without references in an index.

The newspaper, the record of current events, and light literature, the record of current human fancies, are useful relaxations from more serious study. They must be held as incidents, not objects, of life. We must look upon them as we look at the passing pageant, at the varying lights and shadows of the sunshine on the hills, as things to be looked at, admired, and forgotten. We take a Sunday walk to gather flowers by the wayside; there is no use in the flowers, but we are grateful for the ability to admire their beauties; we are better for having done so.

Intelligent attention to details, and a constant aspiration for improvement, have rescued surgery from the barbers and converted it into a science whose devotees stand among the first of mankind; by similar means may be elevated and improved the position and standing of hospital stewards; to point the way is the highest aim and best wish of the writer.

II. In the Field.

Detachments.—Small parties without a medical officer are frequently sent out to guard wagon trains, to cut logs or fuel, for hunting, and for many other purposes; sometimes under a commissioned officer, sometimes under a sergeant or corporal. Whoever is in charge of such parties must be prepared to administer to accidents and minor ills. The change in diet and other conditions is almost certain to cause either constipation or diarrhœa; and the officer in charge must be sent forth, like the apostles of old, with full powers to bind and to loose. He must be prepared to check vomiting before the occurrence of dangerous prostration, and to relieve a stomach of injurious contents. He must be able to allay pain, promptly and safely, and must give rest and protection to inflamed parts. There is no region where a change of conditions and habits may not reawaken the slumbering germs of malaria, and quinine must not be forgotten. Expectorant cough-lozenges will be also required for bronchial troubles. Rheumatic cases are generally sent back to the post, but salicylates and alkalies may sometimes prove useful, and a bottle of turpentine, or other liniment, for slight muscular soreness may well be added as an incentive to massage. Ready-made plasters of mustard or of belladonna frequently relieve local pain and give men a comforting sense of being cared for. Tincture of iodine is frequently useful, but is difficult to pack securely; if possible it should be issued in a bottle with a glass stopper carefully tied in with a string. A rag on the end of a stick for a swab, small enough to enter the neck of the bottle, is better than a camel's-hair brush, as, when lost, another is readily made; if the brush is lost, the amateur medicine-man may feel helpless. A similar bottle of water of ammonia for the stings or bites of insects will be useful. Vaseline, sheet-lint, roller-bandages, isinglass, and rubber adhesive plaster, absorbent cotton, and salicylated jute will make a very complete and useful medical packet.

Each article must be plainly labelled with the moderate and maximum dose and the interval of safety between doses. The packages should be enclosed in yeast-powder cans or other similar receptacles, with a list of contents pasted on the outside of each, and all securely packed in a wooden box. Security and compactness are essential.

In addition to the labels, it is well to prepare a list of contents with instructions for their use, that the officer in charge may take a frequent inventory of his medical

resources and select the required remedy with greater judgment. The following example is intended as a form, to be modified to accord with varying conditions, and with ever-extending experience.

Contents of Medical Packet for Ten Men, Thirty Days. —Ammonia, aromatic spirit of, two ounces. Dose, one-half teaspoonful in a tablespoonful of water every twenty minutes, if required. As a stimulant in fainting or shock. In drunkenness, or vomiting, first give a teaspoonful of common salt and a tablespoonful of ground mustard in a glass of warm water. After the patient vomits twice, give the ammonia, and repeat as required.

Ammonia, water of, two ounces. To bathe the bites or stings of insects. Will blister if confined by a dressing.

Bandages, roller, three inches wide, six. For pressure, protection, and support of inflamed parts, as blistered feet, ulcers of legs, etc.; for sprained joints, first soak the injured parts in hot water for half an hour.

Bandages, triangular, two. As sling to support forearms, also to retain dressings and protect wounds of scalp.

Bismuth, subnitrate of, one scruple, with powdered opium one grain in each paper. Twenty papers. In diarrhœa, first give a tablespoonful of Epsom salts and a teaspoonful of paregoric in a half-glass of water; after two movements of the bowels give one powder, and repeat after each movement, not exceeding four papers in twelve hours. In place of the salts, a tablespoonful of castor-oil with twenty drops of laudanum may be given. Keep the patient in a recumbent posture.

Castor-oil, six ounces. Dose, a tablespoonful. Acute constipation. Combined with laudanum in colic, or diarrhœa. [See Bismuth.]

Cotton, absorbent, four ounces. For an inflamed eye, douche with hot water, and apply a pad of cotton to closed lid; retain with gentle pressure by roller bandage. This will give rest and protect from external irritants. Dress twice daily. May be used instead of sponge in cleansing wounds or ulcers. A pledget soaked in laudanum may be packed in an aching tooth or ear.

Cough lozenges, one hundred. One every hour, if needed, in troublesome cough.

Iodine, tincture of, two ounces. Apply to inflamed tonsils externally, and, in severe cases, internally, with a swab made by tying a rag or a pledget of absorbent cotton on a stick; to the gums in soreness of teeth; to frost-bites; to indurations or painful swellings; to facial erysipelas; to chest, for pleuritic pains; over the breast-bone in painful cough. Prepare a new swab when you would exact one for your own person.

Iodoform gauze, a roll to fit in a half-pound can. Cleanse wounds with boiled water, allowed to cool sufficiently in a covered dish, approximate edges with rubber adhesive plaster, dry the surface, and apply several thicknesses of the gauze. A useful dressing for ulcers, also for abscesses after evacuation of contents.

Ipecac, powdered, half an ounce. To induce vomiting, give half a teaspoonful with copious draughts of warm water. May be repeated every fifteen minutes. In minute doses frequently repeated until nausea supervenes (vomiting is undesirable) in incipient colds; also in dysentery.

Jute, salicylated, one-half pound. A useful protective for wounds and ulcers. Gives elastic pressure under roller bandage.

Laudanum, two ounces. Dose, five to twenty drops, at four-hour intervals. To relieve pain—for local pain, see "Cotton Absorbent." For diarrhœa, see "Castor Oil" or "Bismuth."

Liniment, acetic turpentine (or some other), six ounces. Apply with massage to slight strains or soreness of muscles, chronic stiffness of joints, etc.

Morphine pills of one-eighth grain each, forty. Dose, one. Two, every four hours, is the extreme limit of safety, and if drowsiness last through the period, reduce and postpone the dose. To relieve pain. When the pain is not excessive, one pill every hour until pain ceases or four pills are taken, is safer.

Mustard, ground, two ounces. To induce vomiting, give a tablespoonful with a teaspoonful of common salt in a glass of water.

Paregoric, four ounces. Dose, a teaspoonful in colic, or mild diarrhœa.

Pills, compound cathartic, forty. Dose, two to four. Follow in six hours with Epsom salts, if required.

Pills, camphor and opium, forty. Dose, one every two hours, in colic, or painful diarrhœa.

Plaster, belladonna, six, each four by six inches. For chronic localized pain.

Plaster, isinglass, a roll. For slight abrasions.

Plaster, mustard, six. A counter-irritant for acute local pain.

Plaster, rubber adhesive, two strips, a yard long and one inch wide. To approximate the edges of incised wounds or ulcers; sometimes to retain dressings. Draw snugly around corns, bunions, or ingrown nails.

Quinine, forty five-grain capsules. Dose, one to four. In malarial fever or periodical neuralgia, give four at once as long before expected attack as possible; in fevers, during the sweating stage.

Salts, Epsom, eight ounces. In acute constipation, give a tablespoonful in half a glass of water; in habitual constipation, give a teaspoonful in a glass of water every evening, and, if required, in the morning; a like dose will relieve pain after meals in dyspepsia. In diarrhœa, see "Bismuth."

Salts, Rochelle, four ounces. In urinary derangements, a tablespoonful in a glass of water, to be taken in small quantity at short intervals, to consume this amount every twelve hours. Add two teaspoonfuls of paregoric to the above solution, in lumbago, and other forms of muscular rheumatism.

Soda, bicarbonate of, two ounces. Half a teaspoonful in water in nausea or acid dyspepsia. A teaspoonful in teacupful of water, as a lotion in burns—afterward cover with flour.

Soda, salicylate of, two ounces. In rheumatism, a teaspoonful every two hours until ringing in the ears or relief of fever and pain; afterward continue in smaller doses at longer intervals. Half a teaspoonful is a useful addition to a solution of bicarbonate of soda, in digestive derangements.

Vaseline and zinc ointment, of each six small impervious boxes. Protectives for chapped hands and lips, sunburn, chafing, and abrasions.

To Arrest Hemorrhage. — Secure absolute rest. Douche open wound with hot water. Approximate edges with rubber plaster and apply a firm compress under a roller bandage. If blood continues to ooze, compress the main artery above the wound by field tourniquet or knotted handkerchief and Spanish windlass; and secure surgical assistance as soon as possible.

N.B.—Please preserve empty bottles, boxes, and cans, and return to post hospital with all unconsumed medicines and dressings—when no longer required.

The above schedule will be a useful reference when we prepare to take the field with larger commands. Medicine panniers, orderly and hospital corps pouches contain a very complete assortment of drugs and dressings, but no list can be so complete that a useful supplement may not be made by comparison with such a list and consultation with the individual preferences of the medical officer. Favorite prescriptions can be more conveniently compounded in the stationary dispensary of the post hospital. Splint material, bichloride of mercury in weighed packets for a one-to-two-thousand solution in a quart bottle, carbolic acid, and styptics, should never be omitted when skilled attendance accompanies the command. A lamp with a reflector to concentrate the rays of light, candles, matches, and instruments, must also be provided.

Thorough study must be made of the various panniers and pouches supplied by the medical department, to know the existence, the quantity and the exact location of each article. In case of accidents, as a wetting, requiring that every article be set out to dry, or an

upset that throws all into a confused jumble, the steward should be able to recognize each article and restore it to its original position in pannier or chest. Let the privates remove the contents from a hospital corps pouch and try to replace them; rarely will they be able to buckle the strap at the first attempt. This art of packing is the first great lesson for field service; its daily importance extends from pannier and mess-chest to the army wagon drawn by six mules.

A thorough knowledge of the outfit provided by the medical department will be a useful guide for extemporized substitutes as well as for supplementary provision. The chief defect in the old pannier that came down to us from the Civil War, is the combination in one chest of medicines, surgical dressings, record books, and stationery. The tray containing dressings and instruments had to be removed, with unavoidable exposure of contents, before a dose of medicine could be administered. This suggests a division of the field outfit into medical and surgical, with a small, compact field desk for record books and stationery. Again, it is not wise to constantly expose our total resources to the many accidents of the field. It is better to divide them into medical and surgical packets for daily use, and medical and surgical reserve chests, to be drawn upon, as medicines are taken from the store-room to the dispensary of a stationary hospital.

The amount of supplies for daily use will vary with the probable nature and duration of the service, with the more or less ready communication with the base of supplies. For instance, with a command of several companies, going to occupy a position thirty miles off for an indefinite period, you would take everything enumerated in the Medical Supply-Table; for the same command going on a reconnoitring or foraging expedition to return within a week, and leaving all invalids behind, the supply above indicated for a small detachment would require but little increase of quantities, and the addition of such surgical appliances as the nature of the service might indicate. A permanent camp will justify the transportation of bedsacks, blankets, and folding cots, benches, tables, and chairs; for the bivouacs of the march, these things would be useless incumbrances.

To grasp a thread to guide us through these endless variations, to study intelligently the analogies and differences in the hospital steward's duties when the hospital becomes movable, we will take an eight company post to which an unexpected order comes for six companies with a medical officer and a proper detachment of the hospital corps to proceed to a point one hundred miles away to camp an indefinite period. By the order, thirty days' rations will be taken, and the hospital will be provided with one ambulance and one six-mule wagon.

The Detachment.—Upon the receipt of such an order, the first question to be decided, and this must be done instantly, is which men will go, which remain? This will be determined by the Post Surgeon; but, as in all questions of hospital administration, the steward must be prepared to give an intelligent opinion. The full complement of men at an eight company post is two stewards, an acting steward and seven privates. The allotment for a two company post is a steward, an acting steward and four privates. But in our problem, it is something more than a two company post that is left behind; the sick of eight companies are already here and the more serious cases will find their way back from the field. It is clear that in this division of force there is a shortage to be apportioned between the fractions. This will always be so. Non-combatants are impediments to an army; our problem will forever remain, to get the greatest amount of work from the fewest men. A steward, an acting steward and four privates constitute the maximum force that can take the field. The acting steward goes because the moving command is liable to further subdivision, and his skill may be urgently required.

The three privates left at the post must be thoroughly reliable, capable men. One must cook, one have charge of the wards and internal police, and one do the outside work, and be a general utility man to supply deficiencies everywhere. There is no margin for sickness or inebriation. Of the four privates for the field, one must be an efficient cook, and understand the management of rations; one must be able to drive the four-line ambulance team, and care for the animals. The latter has probably been milking the hospital cow; but, with forethought for such emergencies, there is another private in the corps who can milk, and who must be kept at the post for that purpose. The other two privates for field service are so from necessity—their qualifications may be a subject for regret, but there is no remedy. In the hospital corps, there can be no roster for field service; each man must take the place for which he is fitted.

Equipment.—On the march—as in the desert—no man is a friend. Each man carries on his person the provision for his individual needs; and, transportation being so limited, he only carries enough for himself, and has every incentive to take good care of his own. Under these circumstances, he who goes borrowing will go sorrowing, and the outlook is equally bad for beggar or thief. "We have drunk from the same canteen," awakens sympathies in the heart of the civilian; but to the soldier, the romance of this touching tie is crushed by the reflection that one-half of this friendship was misplaced, that one of the parties was a negligent vagabond who should have had a canteen of his own. This stern reality must be impressed upon the members of the hospital corps; and the men detailed for field service must be warned immediately, to give them all the time possible to provide for their probable necessities.

The official equipment is always ready · the extra pair of shoes, shirt, under-shirt, drawers, and socks are always on hand, ready to be packed with the blanket in the blanket-bag. The hospital corps pouch and canteen hang ready for use with the belt, knife, and scabbard, with the haversack always containing the meat-ration can, the knife, fork, and spoon. The overcoat, rubber blanket, and half shelter-tent with pole and pins, are ever ready to be rolled and strapped on the blanket-bag. When the hospital corps man has put on the above equipments, with a campaign hat and canvas leggings, he may think himself fairly equipped for the field; but there are many little things for him to provide. A hairbrush, a comb, a razor and strop, a tooth-brush, a cake of toilet soap, and a pocket mirror, should all be found in the small compartment of his haversack. Extra buttons, needles and thread, towels, pipes, tobacco, matches, possibly fish-hooks and lines, are things that he must provide now, or go without. In the camp, the men must present a neat and soldierly appearance; each will want shoe-blacking and brush, a button stick, and cleaning material. A few pairs of white gloves, for inspections and musters, will not greatly increase his burden.

Is the soldier's clothing, now seasonable, such as he will require with the changing season? Are woollen stockings, fur gloves, canvas-lined hood, and arctic overshoes, liable to be wanted? It is not enough that the soldier has these things; we must see that they are not left behind. The frozen members will be his own, but the resulting loss of service is an item affecting the general welfare.

The equipment of the hospital corps varies with the command with which it serves. Without specific instructions on the subject, our judgment must be guided by the necessities, conveniencies, and analogies of each case. When mounted, the blanket-bag is useless and inconvenient. Walking, this weight of twenty-four pounds moves with the body; when mounted, the motion of the horse introduces a disturbing element of serious import; the hospital corps man must learn to pack his saddle like a cavalryman, and turn in his blanket-bag for storage, until it is again needed. The rubber blanket may conveniently be replaced by a poncho with its central perforation to pass over the head and retain it in position without assistance from the hands. Vanity may inspire a longing for top-boots, but these are regarded

as useless and unnecessary incumbrances. The members of the hospital corps are mounted only for transportation—their duties are all performed on foot. The infantry canvas leggings answer every purpose when mounted, and, being light and pliable, will not impede the performance of any duty. When the command dismounts to lead up the hot side of a mountain, the feeling of the booted troopers toward the infantry leggings will be one, not of derision, but of envy. As the evolutions of a mounted detachment of the hospital corps will ever be of the simplest, spurs may also be dispensed with.

The accoutrements of a private of the hospital corps form a considerable burden; and his efficiency will be increased by every pound of diminution. What the weight is, and how it may be lightened, are important questions. The belt, belt-plate, knife, and scabbard weigh one and one-half pounds; the empty haversack with knife, fork, and spoon, and meat-ration can, weighs three pounds; the canteen filled with water, weighs four pounds; the hospital corps pouch weighs four pounds; the blanket-bag containing one blanket, one pair of shoes, one dark-blue shirt, one undershirt, one pair of drawers, and one pair of stockings, with one overcoat, one shelter-tent half with pole, and one rubber blanket strapped upon it, weighs twenty-four pounds. The mere adjustment of these things to a man's person, so that his arms may hang naturally by his sides, so that the heavy blanket-bag may not impinge upon the hospital corps pouch and cause chafing, so that the canteen may be readily accessible, is a very difficult problem, further complicated, in savage warfare, by the revolver with which he is to be armed. Every increase of this burden is a serious matter. Leaving the post on a warm October day, he cannot be expected to carry arctic overshoes, canvas-lined hood, fur gloves, and German socks, that he will only require six weeks later.

Without specific provision, it would seem advisable to have a packing-box with the cover secured by a padlock, or a detachment property chest, of sufficient capacity to hold all accoutrements not in actual use. To prevent confusion every article must be marked with the owner's official number. The likelihood of loss will be much less if the many packages are secured in one chest. In a battle, the men detailed for bearers will go upon the field, only equipped with a canteen of water, the hospital corps pouch, the belt, knife, and scabbard. The remainder of their accoutrements and their extra clothing must be left at the temporary field hospital. If secured in a property chest, the men may find their own again after the battle; in case of a sudden move, the chest will be carried along; if the ground be suddenly occupied by the enemy, the Geneva cross may afford this property protection. In no case can individual lockers be carried into the field.

Mounts.—Upon the receipt of the order to accompany a moving command, the number of horses that will be required is a question for immediate decision. A requisition for that number of horses upon the post quartermaster, and for a like number of horse-equipments upon the post ordnance officer, must be prepared for the signature of the medical officer, and the approval of the post-commander. These may not be on hand for issue, but these requisitions will be on record to relieve the medical officer of responsibility for the defective equipment. Never ask for what is not wanted; and we do not want surplus animals to give the small detachment extra work in caring for them. Army Regulations specify the number; but I know of no better illustration, that no general order can obviate the necessity for individual discretion and judgment. With a mounted command, say the Regulations, every member of the hospital corps shall be mounted; but if one of the men drives the ambulance he will be mounted in the driver's seat; the cook will habitually accompany the wagon containing his outfit; to look out for his kettles and pans in case of accidents on the road, he will be much better mounted on the top of the wagon. It must first be ascertained if the quartermaster will send a civilian driver with the ambulance mules, as there will then be required an additional horse.

The number of horses being determined, we must ask for an equal number of complete saddles, curb bridles, watering bridles, and halters; also curry-combs, horse-brushes, lariats, snap-links, double spring snaps for lariats, picket-pins, nose-bags, saddle-blankets, pairs of leather saddle-bags, surcingles, and side lines (or hopples). There is a choice between side lines and hopples. Where Indians may try to stampede the herd, side lines will give greater security; if an animal is a vicious kicker, the side line will render grooming a safe operation. Generally, the hopple is to be preferred; after a fatiguing march, we ourselves would not rest well with a hand and foot tied together. In an exhausting campaign, when the abandonment of worn-out horses was of hourly occurrence, it was observed that those horses went through all right whose riders began the campaign by losing their side lines.

These horse equipments introduce a new kind of property. With an ordnance list in hand, the various articles must be gone over to see that the saddles, bridles, and halters are complete; we must learn to recognize and name the several components, that we may know what to charge for on the muster roll, if any part be lost. The bridles, halters, and saddles must be fitted to the horses, and then an attempt should be made to assign them so that each man may fit his saddle. Now is the time to discover disparities and to remedy them by exchanges with the ordnance officer.

Arms.—If the war is to be waged against savages who do not recognize the Geneva cross, the members of the hospital corps will be armed with revolvers. One revolver and twenty rounds of ammunition for each man will be obtained from the ordnance officer. Each revolver will be loaded with five cartridges when issued to the man; the vacant chamber under the hammer will supplement the safety notch in preventing accidents. The balance of the ammunition must be kept for issue as required. This provision will give the men greater assurance in searching for wounded over a field where a crippled savage may retain sufficient vitality to be dangerous. After camp-fire legends of skulking savages creeping into camp, the man will sleep better for having his revolver within reach. His rest will be undisturbed by the reflection that he would be more likely to kill a good ambulance mule than an Indian, and the camp guard is ample security against such an unfortunate occurrence. All must be impressed with the fact that, in untrained hands, a pistol is a public danger; that the general weal will require the confiscation of all self-cocking bull-dogs, and other private weapons upon discovery. The medical officer may make an exception in the case of a shotgun that may help the hospital mess.

Tents.—The post quartermaster has suitable storerooms for these and keeps them on hand for issue when required. Suitable requisition must be prepared for the signature of the medical officer and the approval of the post commander. Army regulations fix the allowance "in camp or garrison" at three hospital and one common tents. Again, each varying circumstance of climate, season, and soil demands forethought and discretion to adapt a general order to the necessities of a special case. Those hospital tents will be wanted upon arrival in a permanent camp, but they cannot be used on the march. Here, as everywhere, economy of labor, and of time, is an ever-present condition of our problem. In calm weather our entire force can raise a hospital tent with its fly; in a moderate gale, the assistance of a strong detachment from the companies will be required, and, even then, without extreme caution, the iron pin that secures the ridge-pole will be so bent or broken as to render the tent unserviceable. In a driving storm, we will not wish to await such a detail, only to be had after the company camps are in order; nor will we wish to gain for our detachment the reputation of being helpless people who require to be taken care of. The common tent is for the cook, and receives the mess-chest, food-chest, cooking apparatus, and his accoutrements. He must habitually sleep in it, to secure his conveniences from the raids of improvident people who have forgotten

to bring along, or have already lost, the articles of prime necessity in camp life. There will be no room in the cook's tent for anything else. Panniers and other property must be unloaded immediately, for the ambulance and wagon must be parked with the other transportation under the one sentinel, and our animals must not be cheated of a single half-hour of their allotted time for grazing and rest.

For daily use on the march, the best outfit of tentage that can be suggested, that will give the greatest amount of shelter with the least weight, with the greatest economy of labor and time, is one conical wall-tent, one wall-tent with fly, and three common (laced corner) tents. The conical wall-tent gives the largest floor space for the weight, and will afford ample room for the property, for the detachment with equipments, and for sick men besides. The wall-tent is for the steward and acting steward, also giving room for the medical and surgical panniers and the field desk. One common tent is for the cook; the two others will be found very convenient luxuries, not absolutely essential, but sufficiently useful to justify the additional weight of about fifty pounds each. In temporary halts the men need not be fatigued by pitching and repacking the larger tents, the two common tents will afford ample shelter from the sun or rain for the hospital corps and the sick; will give space to open panniers and dispense medicines or dress wounds. With a mounted command that frequently leaves the wagons hours behind, two of these common tents may well be packed with the litters under the ambulance seats. Immediately after halting, sick men can then be made comfortable, the dispensary "opened for business," the ambulance sent away, and the mules given equal grazing privileges with the cavalry horses, which will more than compensate for this trifling addition to their load. These two extra common tents will also greatly increase the capacity of our moving hospital in the stress of emergencies. In a storm or after a battle, the property can be packed into one of them, the hospital corps can pitch their shelter-tents, and the conical tent will shelter sixteen wounded men; and there will still remain one wall and one common tent for operating-room and dispensary.

The medical officer's tent goes with the head-quarters baggage, but it is well to draw it with the hospital tentage and see that it is in good condition before starting. All tents should be marked "Medical Department," with name of post, with a stencil, in such place that the brand may be plainly visible when the tent is rolled. This will prevent confusion, if wagons break and the baggage is mixed with that of other organizations.

Tent-pins must be drawn in a free excess of immediate needs—especially if of wood. The extra ones must be packed in a box and well secured by nails. Those in use will habitually be rolled in the tent to which they pertain. A hundred feet of small rope [ordinary clothesline] for additional stays in high winds will complete our outfit of tentage.

After receipt from the quartermaster, each tent should be pitched in the hospital yard—using only those implements that are to be taken along. It can then be seen that the poles are perfect—and of proper size and length; that all guy-ropes are in good condition; that each tent has the required number of pins; if torn, now is the time for mending. After the condition of each tent has been verified, it is taken down and the poles and pins are laid smoothly along its ridge and snugly rolled in. The roll is then bound by the ropes so that no pin can be shaken out; and the tent is ready for the wagon. This preliminary tent-pitching was once advised by a commanding officer, preparatory to a march the next day. One captain said that, after his twenty years' of experience, this was entirely unnecessary; he would forget nothing. They camped eight miles from the post the next day, when this captain approached with crestfallen air and asked permission to send back a messenger—he had forgotten his tent-pins.

Tools and Implements.—From the quartermaster will be obtained three axes, three picks, two hatchets, two spades, one long-handled and one short-handled shovel, two mess-pans, two camp-kettles, and two galvanized iron buckets. On the march, there must always be found in the ambulance one bucket—for watering the animals by the way,—a hatchet, an axe, a spade, and a pick. With a wagon train, others will help to make the road passable; but, the ambulance being the only wheeled vehicle with the command, you will constantly find gullies to be filled, creek crossings with banks to be sloped, and various obstructions to be removed from your road. Upon arrival in camp the cook will require one axe, and tent-pitching will be done more promptly if you have two for that purpose. When you can get one made, a wooden maul is a less destructive implement for driving tent pins; a section from the trunk of a hardwood tree, of suitable size, with ends supported by iron rings and a handle inserted through the centre, is all that is required. The picks and spades will be useful for trenching around tents, making sinks, and for various other purposes. A small coil of strong iron wire will prove frequently useful in repairing tent fixtures, guying up stove-pipes, etc. In a permanent camp, the hospital tool-chest will be a valuable addition to the outfit. A garden rake and a couple of brooms are policing luxuries that may well accompany the hospital tents for a permanent camp.

Mineral Oil, Matches, Etc.—For ordinary illumination in moving camps, candles are most convenient—least troublesome. For surgical operations and clerical work at night there will be needed a supply of mineral oil for the Diamond reflector lamp. It is customary to take this oil, matches, wicks, etc., from the supplies of the post hospital. In a permanent camp these may be obtained by requisition upon the quartermaster, when candles will be no longer issued as a component of the ration, and hand lamps and oil lanterns will be required.

Rations.—The ration return will be prepared for "The Camp Hospital and Detachment of the Hospital Corps in the Field;" the hospital has certain advantages over other organizations, in the sale of savings to the subsistence department, that may be needed. A list will be made of components as shown in Table III. (page 460), with additional columns for bulk saved, price, and amount. The preparation of this list will always be a crucial test of the steward's discretion, judgment, and experience, an ever-varying, always perplexing problem. The climate, the season, the character of the country to be traversed, the probability of making advantageous purchases along the road, the probable demand and market price for unconsumed components of the ration, are all subjects for consideration now. If the route is to be away from railways, away from the competitive commerce of large towns, as little as possible will be sold to the subsistence department—and the higher prices that can be received in barter by the way be awaited. As the channels of commerce become poorer, the prices of the staple articles of the ration will increase, and those of such agricultural products as may be desired will diminish. You must have food enough to surely subsist your men for the period covered by the return; and a little money will be required to pay for eggs, milk, green corn, etc., that the men may have a variety equal to that of their comrades in the line. The companies leave the post with the fund of each organization to give elasticity to their dietaries; our detachment starts with nothing but the bare ration—we must make and expend a fund as we go along—there is no margin for error or misfortune. Life in the open air and increased exercise sharpen the appetites of the men; and the only compensating increase in the ration is in flour, of which each man receives the entire eighteen ounces, there being no deduction for bakery expenses. Four pounds of baking powder is issued with each hundred rations; and there will be obtained from the subsistence department two dutch-ovens in which the cook will bake his own bread; so that we can safely save four ounces of flour from each ration. This and about one-third of the coffee will be the chief sources

of revenue for this incipient field hospital fund. The following sample statement of the first transactions with the subsistence department can only be a general guide, to be modified to accord with each special case :

Field rations from August 5 to September 4, 189–, inclusive. No. 180.

Components.	Due.	Drawn.	Saved.	Bulk drawn.	Bulk saved.	Price.	Amount.
Pork	8	8	..	6 lbs.	.....	.....	....
Bacon	172	124	48	93 lbs.	36 lbs.	0.078	$2.81
Soft bread	18	18	..	.....	.....	.....	....
Hard bread	12	12	..	12 lbs.	.....	.....	....
Flour	150	104	46	117 lbs.	51¾ lbs.	0 022	1.14
Beans	160	100	60	15 lbs.	9 lbs.	0.012	0.38
Rice	20	20	..	2 lbs.	.....	.....	....
Coffee, green	180	120	60	10 lbs.	6 lbs.	0 231	1.39
Sugar	180	180	..	27 lbs.	.....	.....	....
Vinegar	180	100	80	1 gal.	0.4 gal.	0.13	0.05
Candles	180	180		2.7 lbs.	.....	.....	....
Soap	180	180	..	7 2 lbs.	.....	.....	....
Salt	180	180	..	7.2 lbs.	.....	.....	....
Pepper	180	100	80	¼ lb.	0.2 lb.	0 188	0.04
Yeast-powder	150	150		6 lbs.	.....	....	....
Potatoes	144	144		144 lbs.	.....	.....	....
Onions	36	36	..	36 lbs.	.....	.....	....
Total savings							$5.81

Purchased from Subsistence Department:

12 lbs. ham, at 0 093	$1.12
9 lbs. Y. A. cheese, at 0.113	1 02
5 lbs. lard, at .088	0.44
12 lbs. canned corned-beef, at 0.15	1.80
¼ lb. mustard, at 0.422	0.11
Total	$4.49
Balance in cash	1.32

In the above transaction, including lard and cheese, there is no reduction in the weight of animal food. This will always be a safe provision ; the vegetables bought along the road will be starchy foods, substitutes for the flour ration only. The saving of flour is large, but within the limits of prudence when so large a percentage of the pound of vegetables can be drawn in potatoes. The prices are taken from a Commissary Price List current at the time of writing. The relative price of ham, as compared with bacon, is unusually low. Beans are saved instead of rice, because at the unusually high price the fund receives five cents more than would have been received from an equal number of rations of rice at five and one-half cents per pound ; the price of a quart of milk or a half-dozen eggs is an important gain for our fund in its birth struggle. The soft bread is drawn for use during the first few days of the march—as much as will remain fresh until consumed. The hard bread provides for accidents or irregularities of the march which may deprive the cook of the time necessary for baking.

As soon as received, the ham will be boiled and some beans nicely baked—the pork was drawn to bake with them. These things can be more conveniently and better done on the range of the post hospital, and will greatly relieve the cook upon the march. Two slices of bread, a slice of ham, and a little mustard will make a sandwich to nicely fit in each meat-ration can ; and, with a bit of cheese, a little paper of salt, and an onion, will provide the men with a very satisfactory lunch at each mid-day halt. When the ham is gone, the canned corned-beef will replace it in the sandwich. There should be a mess-pan filled with the baked beans, which, served cold with vinegar, will economize time for the cook and prove a useful and popular addition to each early breakfast.

When the rations are drawn, an allowance for five days will be put in the food-chest, and the remainder boxed up so that the cook can only have access to them by application to the steward. In this way waste, and consequent shortage, will be brought to the steward's attention before the matter becomes serious ; the rations will also be preserved in much better condition. The latter is especially true in regard to bacon, which deteriorates in quality and loses weight during wagon transportation.

The uncertainties of the future compel us to draw the meat ration chiefly in bacon ; but, as occasion occurs, the commanding officer will order the purchase and issue of fresh beef, when his order will be required for the camp commissary to take back an equivalent in bacon. Otherwise the detachment will have received double rations, the accounts of the commissary officer will be confused, and, if he attempts to straighten the matter by deductions from future returns, so much time will be required that the detachment may be split up into fragments, and a matter, simple at first, may become too complex for a just settlement.

The five days' allowance of coffee will be roasted in the hospital range, ground, and secured in close cans in the food-chest.

The Field Desk.—The folding desk furnished by the medical department is too small to contain a sufficient supply of blanks and stationery, and must be reserved for current work. In the absence of one specially devised, the ordinary company field desk furnished by the quartermaster's department will answer the requirements. In laying out the blanks to pack in it, we must consider that the post hospital is a camp hospital that circumstances have rendered permanent ; that the only change has been that record books have been substituted for the retained copies of various returns and reports which are still kept in the camp hospital ; and that a correspondingly increased number of blanks will be required. No meteorological observations are required from the moving hospital. We must review the various departments with which we will have to deal, the various kinds of property for which we will have to account. Soldiers will enlist, be transferred to other commands, be discharged, die, be mustered, be paid, as at permanent posts ; sick men will be transferred to other hospitals ; the detachment will be reported monthly ; there may be lists of wounded, and reports of epidemics. Clothing and equipage, quartermaster's stores, and ordnance property, will each require a quarterly return. Changes of accountability will necessitate blank invoices, receipts, and requisitions ; also returns of medical and hospital property. Completed cases and the hospital fund will be reported monthly. We shall need ration returns, requisitions for fuel, memorandum slips, a blank book for orders, letters, and endorsements, a copy of the Epitome of Current Orders and Decisions, corrected to date. With the exception of ink (which must be packed where the damage will be less in case of breakage), the stationery may also be packed in the field desk.

The Ambulance.—We must see that everything is in serviceable condition ; that no nut or brace is loose ; that the water-keg will hold water ; that there is provided an extra tongue, the required number of litters and rollers, a bucket, a lantern, an axe, a hatchet, a wrench, and a box of axle-grease. All bearings are lubricated before starting.

The Army Wagon.—The busy day of preparation may well be closed by having the wagon brought to the hospital and loaded, ready to pull out with the train in the morning. This will obviate confusion and delay at the start ; the proverbial slip upon the threshold not only will bring misfortune, but is one in itself. With the interval of rest after loading, we can review our work, discover omissions, reconsider the relative importance of things taken and things left behind, and make desirable corrections before the hour of departure.

With the average of American roads, thirty-five hundred pounds is the prudent maximum load for a six-mule team. The wagon box has a floor space of three and one-half by ten feet, and can be loaded to a height of somewhat over four feet, allowing for the curve of the bows. In determining the load, bulk as well as weight must be considered. Heavy packages must be placed nearest the ground ; articles required daily must be accessible without removing the entire load ; all must be packed as firmly and compactly as possible. The fol-

lowing list of packages and approximate weights may be of use as a general guide :

	Pounds.
Rations	550
Food-chest, mess-chest, dutch-ovens, mess-pans, and camp-kettles	360
Medical and surgical panniers	250
Medical and surgical reserve chests and hospital stores	500
Field desk, packed	100
Tentage for the road, with fixtures	350
Axes, picks, shovels, spades, guidons, etc.	100
Tool-chest	90
A table and two benches, with folding legs, and four stools	100
Twenty-four blankets, in two cases	100
Twenty bed-sacks and twelve hair pillows	125
Stoves and pipe	125
Twelve folding cots	400
Twelve folding bedside tables	100
Folding dining table	125
Twelve folding chairs	125
Commode set	35
Pack saddle and fixtures	45
Twelve mattresses	300
Three hospital tents, flies, guys, and pins	600
Total weight	4,440

It will be seen how readily a prudent load is exceeded ; and the space is exhausted long before the maximum of weight is reached. The question is, What can be left behind with least inconvenience ? The twelve mattresses are not essential ; the folding cots are comfortable without them in warm weather, and in cold weather a folded blanket under each patient will insure sufficient warmth. Bed-sacks stuffed with hay or straw make clean, soft beds ; and, with rubber blankets to cover damp ground, the cots may be dispensed with. The ingenuity of the hospital corps will improvise a bunk if one be required. The bedside tables will never be missed. The folding chairs may be reduced to two or three. The dining table is a nearly useless luxury, as the lighter one with folding legs, made by the carpenter for use on the road, is a fair substitute, requiring less space. Pillows are so convenient for steadying an invalid's head, for supporting an inflamed limb, etc., that their exclusion must be a last necessity. The pack-saddle is carried in the wagon for use with expeditions without wagons. The quartermaster will provide an animal when required ; and you need not burden your detachment with another mule until it is needed. With the tentage for the march, you can improvise a very satisfactory camp hospital by attaching the shelter-tents to the common ones for the use of the detachment, and reserving the conical wall-tent for a ward. One hospital tent will be a great convenience—but all three may be left behind if necessary. The medical and surgical panniers are consigned to the wagon as the orderly pouch, the instrument and emergency cases will be sufficient for all accidents on the road ; and the reduction of the ambulance load will be another ever-present and difficult problem of the utmost importance.

Civilian Teamsters.—Army regulations direct that one member of each detachment of the hospital corps shall be designated as ambulance driver, evidently a wise provision in case of long-continued hostilities ; but while the corps remains on a peace footing it will generally be wise to accept the services of the civilian driver employed by the quartermaster, and keep the designated ambulance driver for other duties. The number of privates that can be taken into the field is so small that this increase of force is of great advantage ; and to keep an extra man at every military post throughout the year to provide ambulance drivers for a field service aggregating but a few weeks, would not be an economical policy. The designated ambulance driver may be able to guide the mules safely along the excellent roads about the post, and still be unfit to follow a cavalry command across the country ; without the possibility of testing his skill beforehand, to entrust sick men to his care will involve great risks. Again, the mules cannot be kept for the exclusive use of the medical department—economy requires that they be used for other purposes during a great part of the year ; and the quartermaster does not like to discharge the civilian employee for so short an interval, as a good four-line driver is difficult to secure, and the man will find employment elsewhere.

The quartermaster will send the mules in the harness to which they have been accustomed ; and it is better to leave behind the hospital harness. Your collars may fit the mules, but a new collar is like a new boot—a long march is not the proper time to begin its use ; and if your collars have been moulded by use to fit one team of mules, the next set of animals will surely be of a different size.

At the last moment, there may be another little question to decide. Each organization has its own teams, and there will be no separate mess for the quartermaster's employees ; the teamsters mess with the companies to which they are assigned. The drivers of the ambulance and hospital six-mule team will desire to turn in their rations and mess with the detachment of the hospital corps. These men must live somewhere, and cannot well cook for themselves. A company commander may take them as a favor that will be asked with hesitation ; but that company may be detached the next day and the trouble recur. The messing of outsiders in the hospital is prohibited, but these men are considered as civilian attachés to the hospital corps, who, if they turn in their rations, may properly enjoy the services of our cook. This question has never been the subject of an authoritative decision, but such a ruling by the medical officer is supported by so many good reasons that it is likely to be sanctioned by higher authority if the question is ever raised.

The Start.—At least an hour before the time fixed for starting, the men must be out to feed and groom their horses. Each man must care for his own—for they are strangers yet and prone to misunderstandings, and this early intimacy will beget a useful friendship. After stables the last home breakfast will be taken, each man provided with a mid-day lunch, saddles packed, canteens filled, and accoutrements made ready. The water-keg should be filled from the hospital cooler and wrapped in a wet gunnysack before being placed in the ambulance—to keep it cool by evaporation. The animals must be given an opportunity to drink. We will take a final inventory of the contents of the wagon and ambulance, and see that the emergency case and the instrument case are in the latter. The men will fall in for a final inspection, and, if there are no corrections to be made, may rest at ease until the warning call, "Boots and saddles." The wagon, with the cook on top, will pull out to take the place in the train that may be assigned by the sergeant in charge. The ambulance will follow in rear of the troops. The hospital corps, except the orderly who attends the medical officer, follow close behind the ambulance.

Each start from camp will be a repetition of the above, with the addition of repacking and reloading whatever has been taken out for use. There is an instability about camp life that renders it important that, before sunset, everything about the hospital be so arranged that an order to move in the darkest part of the night can never cause delay, confusion, or loss. Breakfast is a great promoter of cheerfulness ; and, if the cook has done his baking, if he has his fire ready to light, his coffee ground and in the pot, no order to move out will be so sudden as to take the men out of camp without at least a piece of bread and a cup of hot coffee—as well as a suitable lunch in their haversacks.

Habitually the cook must be called a sufficient time before "Reveille" so that the men can take breakfast while the animals are munching their grain ; he can then wash and repack his dishes while the others are grooming, and be ready to assist in striking tents and reloading. It is customary to have all the tents in camp go down at a bugle-note ; but the medical department has not men enough to handle all its tents at once, and it will be necessary to have the smaller ones repacked, and display our military precision upon the circular wall-tent. To have a place for everything and assign to each man his allotted share of the work—so that he may know what to do without orders—is the best means to insure celerity, to avoid confusion. After everything is reloaded, we will move our command a short distance away and go over the ground carefully—with a lantern if necessary—to see that

no tent-pin, knife, fork, spoon, cup, or other article has been overlooked.

THE MARCH.—The detachment will be observed as it moves out. The restless horse is probably uncomfortable; the girth has the nature of a compound pulley—an injudicious man may pinch the back and cause an abscess in a short time; if a horse shakes and tosses his head, the curb strap may be so long as to allow the curb to turn forward and strike the upper incisor teeth. There will be a short halt after the first two miles and at the end of every hour, when the feet of the animals must be examined, girths tightened, if necessary, and saddles readjusted.

Sick men are given a pass from their company commander and fall out to await the ambulance; cavalrymen are generally accompanied by a non-commissioned officer. The surgeon examines each man and endorses his recommendation on the pass. Each man who is excused from any duty by the surgeon must appear on the hospital reports, as in the post; the steward must have a suitably ruled blankbook and enter his name and the other required data at once—as he may never see the man after he leaves the ambulance. Men faint from heat, or suffering from other slight ailments, only need a ride to camp, and may not appear again on the sick report. When admitted to the ambulance, the cavalryman's horse, arms, and accoutrements are taken back to his troop by the non-commissioned officer who accompanied him; the foot-soldier is directed by regulations to turn in his arms and accoutrements before leaving the ranks. In actual war, these provisions are essential, when straggling becomes a considerable evil, and a provost guard arrests all men out of the ranks without written authority; but are generally neglected under the conditions of Indian warfare. The writer has followed marching columns more than twenty-five hundred miles without having seen a company commander's pass or an infantry soldier carrying another's arms or accoutrements. The medical officer will not raise questions of discipline in other organizations until the results seriously affect his immediate command. Common sense and the Golden Rule are useful supplements to army regulations in the face of perplexing conditions. For example, an infantryman is overcome by heat, he feels dizzy and short of breath, he does not know what the matter is, but thinks that if he can rest a moment he will be all right. When the ambulance reaches the spot, we will find him there. His ghastly face bathed in perspiration tells the whole story. There is no question of a pass; we will give him restoratives and load him—and his trappings—into the ambulance. This converts our ambulance into a transport for arms and munitions of war, despite the Articles of the Geneva Convention, in violation of a paragraph of Army Regulations which specifies what may be carried in an ambulance; but any practical board of survey will make us pay for that gun if we throw it away. Of course, in civilized warfare, should we fall in with the enemy, there would be serious incongruity between the cross on the sleeve and the arms in our hands. Truly, circumstances alter cases and demand the exercise of a rational discretion. When sick men start from camp in the ambulance, their arms and accoutrements belong with the baggage of their respective companies, and we must refuse to receive them, for the ambulance would soon become an ordnance depot and be seriously hampered in its legitimate functions.

Each hourly halt will give an opportunity to adjust defects. The ambulance curtains can be raised and lowered to accord with the changed direction of the sun. The animals must be offered water frequently, if the chance occurs. If there be grass, riding animals must be relieved of their bits and allowed to graze. This kindness of his master is appreciated by the horse as highly as the dainty morsels snatched by the wayside; and the friendly relations established between man and beast promote that cheerfulness of spirit so necessary for protracted physical endurance. The man who takes every opportunity to gather a few handfuls of mesquite beans or any other dainty relish, and allows his horse to eat from his hand, will rarely be compelled to abandon a worn-out animal and continue his journey on foot.

TEMPORARY CAMPS.—Each arm of service has its own normal rate of speed. The cavalry, including halts, will average four miles an hour; the infantry, three miles; the mule train, two and one-half miles. The train cannot be hastened; and it is very irksome and fatiguing to hold back a marching column to the slower rate. Without imperative military reasons, the command will not be kept together. Starting together, with a purely cavalry command, we will complete the march of fifteen or sixteen miles and arrive at the camping place a full three hours before the train. With a mixed command, the ambulance is kept in rear of all, and will arrive with the infantry two hours before the train. The cavalry are sometimes held back for morning grazing after the infantry and train have resumed the march; in this case, the ambulance will remain with the cavalry until the infantry are overtaken, when, keeping in rear of the entire command, it will arrive with the infantry as before. The adjutant indicates the location of the hospital, to which the detachment will proceed immediately. Each man will unsaddle and secure his horse with hopples and lariat in the immediate vicinity. In a scorching sun, the backs of animals, moist with perspiration, must be protected until dry by the unfolded blanket secured by the surcingle. The ambulance is now unloaded and sent to the place where the train will be parked when it arrives. All this will take but a few minutes; and the ambulance mules will soon be relieved of their harness and grazing at ease. With helpless sick men, or in stormy weather, the ambulance may be left at the hospital until other provision can be made. The reason for not constantly leaving the ambulance near the hospital is that his wagon is the teamster's only shelter, and it is better that he should lodge near his mules. In threatening or stormy weather, or where artificial shade is required, the shelter tents may now be pitched.

The topography of the site of the future hospital will now receive careful attention. The location for each tent will be marked, briars, weeds, and rubbish removed, trenches dug for the sink and the kitchen fire, fuel and water obtained, and the cook's fire made ready for the match. The location of the tents is a matter of some importance. The general location of the hospital has been fixed by the commanding officer, but the ambulance officer has discretion as to details. High and dry ground will always be selected. A tempting greensward at a lower level is always a dangerous experiment; the place is smooth and green and level, because storm waters concentrate there from every shower. Should our command have been preceded by another, it may be compelled to occupy the old camp; and there will be a temptation to utilize the labor of our predecessors. But man is a mischief-breeding animal, and the old campground has its dangers. It will be more prudent to clear away fresh brambles and pitch our tents to the front or rear, to the right or left. The tents will afford sufficient shade—and it is better to avoid that of trees, for the natural shade is grateful to numerous insects who may resent our intrusion; for, if well apart, the tent and the tree will afford shade, and neither lightning nor high winds need cause anxiety. We will avoid ant-hills, for a ruthless war will result to our disadvantage.

We will have a constant order in the arrangement of our tents and a settled place for everything, so that the men may learn to go into camp almost without orders. The kitchen should be somewhat in rear and on the leeward flank, that neither sparks nor smoke may be carried toward the other tents. If the camp be surrounded by dry grass or weeds, they must be immediately cleared by a belt wide enough to give protection from the spreading fire of some injudicious neighbor; our own kitchen fire must be surrounded by a belt of fresh earth. The sink must be decorously screened by bushes or a common tent.

The water-supply must be examined. If from a spring, a reservoir will be prepared—with gravelled bottom if possible—large enough to allow the water to be dipped

with a camp kettle without roiling. If water is to be obtained from a brook, an approach must be made so that the water may be dipped from the main current, and not from a foul eddy. If from a lake, the water may have a brackish taste from saline ingredients; if so, a pit may be dug on the beach that the fluid may percolate through the soil before being used. This will improve the matter, but the best will be bad enough. The surroundings will be examined carefully, that we may not be drinking the seepage from decaying animal matter. If the troops begin to use the slope above your water-supply as a decorous retiring place to answer the calls of nature, the steward will report the matter at once to the surgeon, that the matter may be stopped before a passing shower can bring down the soluble excreta. Other organizations must prepare sinks, as the hospital has done, and be compelled to use them. The perspiration is now dry on the backs of the animals, and the blankets can be removed, folded, and placed with the other equipments. The animals can be watered and moved to fresh circles of grass.

The experience of a few days will enable all these things to be accomplished speedily, and the men will have a considerable rest before the arrival of the wagon. When this comes, remove only those articles that will be needed. The whole force proceeds to pitch the tents and store the property and equipments within. The cook then unpacks his kitchen, lights his fire, and proceeds to prepare dinner. The other men will now dig a small trench around the tents, banking the earth so that no overflow can reach the interior. These trenches will be of little use without a suitable outlet, a problem in hydraulics so simple as to be sometimes overlooked.

The care of animals in camp is, as yet, a new problem for the hospital corps. Without experience, or definite instructions, the subject can only be discussed in a general way. As a first principle, each man must water, feed, and groom his own horse. This will promote a tie of comradeship between man and beast that will insure a better-cared-for, more serviceable animal. Then, the established hours for stable duties must coincide with those of the rest of the camp, for the trumpet calls will then be a reminder to prevent neglect, and will fix boundaries beyond which punishment will not be deemed unjust. The question of guards is more obscure; no troop commander will accept the responsibility for nine additional animals, and the mingling of these animals with a troop herd will be justly deemed a nuisance. These animals must be sent sufficiently far from camp to secure good grazing, and our four privates cannot furnish a herd guard. The most feasible solution of the difficulty seems to be, to put the horses on the same footing as the ambulance mules with the quartermaster's train. Two or three lariats twisted together and stretched between the wheels of wagons and ambulance will make an improvised picket rope of sufficient length and strength. The end of the ambulance tongue is not a proper place to tie up animals. From overlooking this plain fact, the writer once found himself in the sands of Southwestern Texas, sixty miles from the nearest post, with the only wagon tongue snapped off at the hounds.

Notwithstanding the midday lunch, the men will be ready for their dinner as soon as the cook has it prepared; and, in the uncertainties of field service, a delayed meal may be a lost one. It is impracticable on the march to serve three daily meals as in the post; and this combined dinner and supper, being the heaviest meal of the day, should be served, preferably, two or three hours before sunset. Early hours are observed in camp, and ample time for digestion before retiring should be given. The cook, also, will have ample time, by daylight, to put things in readiness for any unexpected order to move.

Tent ropes vary greatly in length with different degrees of atmospheric moisture; if dry when the tents are pitched, a shower in the night will so shorten them as to loosen or pull out the pins, when a sudden gust of wind may bring down the tents. The men must be instructed to promptly adjust them, as a delay may cause a very unpleasant disaster.

The steward's tent and that of the medical officer should be distinguished by planting a hospital guidon in front of each, for there may be sick calls in the night and the messengers—who will carry lanterns—need not arouse the other staff officers and the entire hospital.

With everything in order, the later afternoon and evening may be spent in idle revery; in watching the lengthening shadows, the twilight deepening into night. The chirping of insects, the murmur of the brook, the rustle of the leaves in the growing stillness, become audible music, a droning lullaby, inviting to repose. This is the dolce far niente of camp life. At an early hour our little world is wrapped in unbroken slumber, the occasional challenge of the sentinel only rousing to a dreamy consciousness that all is well.

Permanent Camp.—The bivouac for a night may sometimes become a resting-place for weeks and months. Sometimes the canvas is gradually replaced by more substantial structures, and the bivouac has passed through all the stages of development to a military post. When it is known beforehand that the position is to be occupied for a considerable period, additional provisions for this more permanent camp can be begun before we dismount at the end of our march. The location will be selected with more care with reference to the convenience of the command, the surface drainage, accessibility to water, and possible meteorological conditions. Sedimentary deposit on one side of a bunch of grass, floodwood or rubbish piled against a tree, a general inclination in one direction of the undergrowth, especially of dead brushwood, are each sufficient to tell you at a glance that the apparently driest of deserts is subject to overflow. That lightning will not strike twice in the same place is a very unreliable proverb. What has happened once is likely to happen again. Like causes have like results, even with the uncertain weather. Year after year a hail-storm will ruin the flowers at one end of the garrison and spare the rest. A belt of fallen timber marks the path of a hurricane; our tents will be safer to the right or the left. Bowlders, or cobblestones, spread out at the foot of the hill, mark the limit of a descending avalanche; it will snow again; there are more stones above. The perpendicular face of the terrace has not crumbled before the slow processes of rain and frost; it has been cut away by a rushing torrent; more floods will come; more land will fall.

Where prevailing winds are dry the grass is greener on the lee side of the hill. We may profit by the same shelter. The cool, refreshing breeze from the mouth of a cañon tells us that is not a good place for a winter camp. Ravines are natural outlets for storm waters; we will avoid the lowest depression. Neither will the exposed divide be selected. Beware of a spot where unusual vegetation indicates moisture; it is the probable outlet of cold springs that no system of drainage will render habitable. In itself, a strong turf is of little importance, for it will soon be worn away, but if the grass is scattered and wiry, or is replaced by reeds or rushes, we will avoid the place; too cold for healthy grass, it cannot be made a sanitary dwelling-place.

As our stay will be protracted, more room will be required, and therefore the increased space may as well be cleared at once. A clear passage must be left between the tents for convenience, and that an accidental fire may not endanger all. The sink will be of greater depth and farther away. The tents should face away from prevailing winds, generally toward the east, or between the east and south. Square tents should present a fly to the hot afternoon sun. Shade trees in our dooryard will give the place a cheerful, homelike appearance, and will be so utilized when practicable.

There is a monotony in life in a permanent camp that is sure to grow irksome; everybody will long for the novelties of the daily march. This is aggravated by absolute idleness, and work must be economized so as to provide the men with a few hours of occupation each

morning for as long a time as possible. After the essentials are provided, diligence is no longer a virtue. It is unwise to do to-day what can be put off till to-morrow, for the time will come when even drills will cease to be a diversion. If carefully planned, a few hours' work each morning after the general police will provide many comforts and luxuries.

The kitchen needs, first of all, a place to store rations where they will be secure, out of the way, and preserved in better condition than they can be in a tent. A pit of suitable size can be dug with a passageway into the tent if practicable. It will be covered first with logs or poles, then with brush, preferably with the leaves on, and then with such a thickness of earth as will render imperceptible all changes in the external temperature. We must be careful to provide ample surface drainage; and if there is danger from ground water, we will carry a narrow trench, somewhat deeper than the cellar, to a proper outlet. If cobblestones are at hand, this drain can be partly filled with them, the sod cut from the top laid on the stones, and the remaining ditch filled with earth. Poles laid longitudinally so as to leave interstices, may take the place of the stones. If necessary, this storeroom can be made above the ground level; but more labor and material will be required, and the same uniformity of temperature will be attained with difficulty.

An oven is a very useful addition to the kitchen. Men grow tired of baking-powder bread, and good baker's bread will be deemed a luxury. If an oven be provided, with a cool cellar where stock yeast can be preserved, your cook will rival the post baker in the quality of his bread; meat can be roasted and beans baked. With brick or stones, lime and sand, but moderate skill is required to construct an oven; but we can do without any of these. I have seen good bread baked in a hole in the face of a bank, where the soil was but moderately cohesive, with a perpendicular shaft sunk for a flue. On a level prairie, a foundation can be raised, or an excavation made for a hearth on which to pull out the coals. An empty barrel will serve as a form around which the clay can be packed; a length of stovepipe will give draught, or a chimney can be built of sticks and mud. The wall must be thick to retain sufficient heat. A piece of sheet iron, or an old oil-can, will do for a door; in the absence of these, stones can he piled in the opening and banked with earth when the oven is used. The first fire will burn out the barrel, but the clay will be hardened and make a very durable oven.

The kitchen fire admits of various improvements. Strips of sheet iron with holes for the kettles may be laid over a trench. This, with a couple of pieces of Sibley pipe or a rude chimney at one end, and a short piece of iron at the other to regulate the draught, will answer nearly all the purposes of a stove. The supply of sheet iron, or tin from old oil cans, is the only limit to the length of this trench, which may be extended across the interior of a tent, which will be sufficiently warmed thereby in the coldest weather. This system of heating may sometimes be conveniently applied to other tents, care being taken to bury the iron cover where it passes under the canvas.

Poles, supported by crotches, can be put up in convenient places, where various articles can be hung when not in use. This preserves the articles in better condition and gives an unobstructed ground space. For lighter articles rope or wire answers the same purpose.

Tent-pins can be replaced by posts firmly planted close to the tents, so as to minimize the hygroscopic variation of the ropes, lessen obstruction between the tents, and give greater security. The tent-pins will be repacked for use when the march is resumed.

In hot weather, arbors can be built over the tents by weaving green bushes into a substantial framework of poles. It is better to make the arbor large enough to shade the tent without lateral walls, as the latter are in the way, and when the leaves get dry increase the danger from fire. With this protection from the sun, the square tents no longer need the flies, which can be used as awnings to increase the dry ground space.

When there is a scarcity of canvas, and at the approach of cold weather, improvised shelters will be constructed. In choosing an architectural design for these, it is well to study the methods of the native population. Their experience is longer than ours, and they have arrived at their present practice after many errors, into which we may fall if we depart from their plans.

On the prairies the scarcity of timber and the prevalence of cold winds render the dug-out a favorite dwelling. But when man burrows in the earth, extra care must be taken to secure dryness of soil, ventilation, and sunlight. Life in a dark cavern will in a short time make men look like jail-birds.

Sods used like brick, make an exceptionally warm dwelling, but involve the expenditure of more labor. With an earth-covered roof a sod building can be made frost-proof and replace the cellar where the nature of the soil forbids an excavation.

The log hut, chinked and plastered with mud, also makes a warm dwelling, but windows are difficult to devise, and sufficient ventilation and light will not be provided without a carefnl supervision.

In milder climates poles planted in the ground, with the interstices plastered with mud, will form the walls, and the combined shelter tents of four men will make the roof of a very serviceable hut.

The tent is a very expensive habitation, and when the camp is to be of considerable duration, the canvas will be replaced by the more economical frame structures, and the conditions of a post hospital will be approximated. The camp hospital is the germ that by development becomes the post hospital; it is the atom that by multiplication produces the field hospital. A ward to shelter patients from the elements, a kitchen where their food can be prepared, a dispensary where medicines can be compounded, an operating-room where wounds can be dressed without disturbing other patients, a storeroom for property not in use, a dormitory for attendants, a place for the dead, and an office where the records can be kept, are the essential elements present in all, and the administration is essentially the same. The ward of the post hospital, with its perfect ventilation, its cleanliness, and its abundant sunlight, is the type, the model toward which we aim. The variations in management are but efforts to obviate the imperfection of our means.

The hospital tent, covering a ground space of 210 feet, and containing a cubic air-space of 1,620 feet, is intended to accommodate six patients. The canvas is practically as impervious as the walls and ceiling of the permanent ward; some air may percolate through it, but the close meshes act as a filter to detain impurities, and the air that passes through from without can no longer be deemed pure. With a floor space and air space hardly sufficient for two patients divided among six, it is evident that the openings for ingress of fresh air and egress of foul air demand more constant attention. In summer, the side walls are raised, the end walls rolled back, and the patients are practically in the open air; but in winter, with the sod-cloth sealed down, with the flaps carefully closed, with a stove consuming oxygen rapidly, to maintain sufficient warmth and keep the air fit for respiration in a hospital tent containing six patients, becomes a very difficult problem. For convenience of administration, the tents are sometimes joined, end to end; but, although the ventilation of each is kept independent of the others, it is unwise to subject more than two tents to a common fate, as the chances for error increase with the number, and the law of diffusion tends to produce a common atmosphere in all.

In the field, the soldier carries his personal effects in his knapsack, and prefers to bring them with him to hospital. As the allowance of transportation limits the amount of hospital bedding, he may as well use his own blanket, leaving the few hospital blankets for emergencies, or supplementary provision. If the case be infectious, the blanket and clothing have been contaminated before admission, and are better kept away from the company baggage. They can also be disinfected before the owner is returned to duty.

Bedsacks stuffed with hay or straw are better than

mattresses for field use. When soiled, the bedsack can be washed and refilled; to rejuvenate a hair mattress is beyond our resources.

Laundresses and matrons are unknown in the field; every soldier washes his own clothes; and the laundry work of the hospital—as well as the clothing of helpless sick men—is a legitimate part of the hospital work to be done by members of the hospital corps. If the articles are pounded in a barrel of hot soapsuds, secured to a rope and allowed to float in a running stream for two hours, and then hung up by the corners to drip and dry without wringing, the matron and her sad-iron will not be missed.

Battle.—Behind the line of battle, the first dressing station, the ambulance station, and the field hospital will each fall under the supervision of a hospital steward, and a previous consideration of the elements of the problem will facilitate the solution. Great battles are generally foreseen, and the location of the field hospital fixed by the medical director; but often the movements of the enemy are unknown, and an unexpected struggle requires immediate action. The medical officer may be searching for a wounded artery, and the selection of suitable locations, and other preliminary arrangements will devolve upon the steward, who must be prepared to act intelligently and promptly. To afford the speediest aid with the least labor, and to keep out of the way, are the chief factors governing our choice of positions. If we obstruct the road with the ambulances and delay the advance of artillery, ammunition, or reserves, we may give the enemy great advantage and ourselves more work.

The Field Hospital.—This must be sufficiently far in rear to insure the wounded from anxiety or further danger; but, with this object attained, as near as possible to the fighting line, for bearers and ambulances may have many round trips to the front, and an extra quarter of a mile will soon amount to a day's journey. From one and one-half to three miles is generally the proper distance from the line of battle. Previous knowledge of the terrain is of great advantage, but if we know what we are looking for, much topography can be learned at a single glance. Water, firm ground, easy access from the main road, and protection from the missiles of the enemy are the main requirements. A farm-house or other buildings that may supplement the tentage in case of need, will be a convenience. These things are generally found together. A belt of timber or a range of hills may allow of a near approach to the scene of operations; an open country, or an unstable front, may render a greater distance necessary. It is well to be a short distance away from the main road, that it may remain unobstructed by waiting ambulances. Then, reserves must use the road in passing to the front, and they will not be cheered by a close inspection of the unpleasant results of war; or, these marching columns may be observed by the enemy, who may experiment with long-range artillery to our discomfort. Strategic positions, clusters of trees, stone walls, and other defensive points will also be avoided, for an ebbing tide of battle may pass that way, and military necessity will ignore our field hospital now anchored there by a multitude of wounded men.

The location being chosen, gates will be thrown open, fences and other obstructions removed, ditch crossings bridged, filled, or graded, so as to give easy access to the front and rear of the proposed hospital. There should be a continuous road for ambulances to pass in and out without backing, turning, or passing one another. Then startled mules can have free headway, and there can be no annoying blockades or distressing accidents.

The operating-room may be a tent-fly stretched as an awning, with a small tent to give further protection to instruments and dressings. These should be to windward of the roads that the dust of passing ambulances may not cause trouble. They should also be screened from observation, as patients awaiting treatment will not be cheered, and those already cared for will be made sick and faint by a view of the operating-table.

The kitchen should be between the operating room and the wards, as it must furnish supplies to each. Boiling water and water boiled and allowed to cool in covered dishes must be constantly on hand in large quantities, for no well or spring will furnish water of sufficient purity for surgical purposes. There must also be a constant supply of hot tea, hot coffee, and hot beef-soup for patients as they are brought in. Hungry men will not do good work; and meals at all hours must be served to drivers, bearers, and other attendants. The field hospital kitchen is a busy place on the day of battle.

There should be two wards—one to receive the wounded from the field, and one to receive them after they have been cared for by the surgeon. The ward for patients awaiting treatment may, in fair weather, be in the open air with such natural or artificial shade as may be required; in stormy weather, tents must be pitched or a convenient building utilized. With a scarcity of canvas, it is better to use the buildings as a receiving-ward and reserve the tents for the more lasting occupation by patients from the operating-room; for the sanitary condition of the tents is under control, and the pathological history of the best of farm-houses is a subject for suspicion.

As the wounded are received from the field, each man will be provided with a card—if he has not been already provided with one—on which is entered his name, rank, company, regiment, hour and day of admission, and any other required data that can now be obtained. This card goes with the man to the operating-room, where is added the diagnosis and treatment, and then to the permanent ward, where entries are made in the register of patients, list of wounded, etc., and the hospital number is added to the card.

As the field hospital is but a temporary halting-place, liable to advance or retreat at short notice, a final disposition of the cases must be made at every opportunity, and, without specific instructions from the surgeon, every case is awaiting transfer to the division hospital at the base of supplies; and the transfer slip may be prepared at once, that transportation need only wait for the entry of date, destination, and surgeon's signature. An entry in the register of the final disposition, as death, transfer to division, or general, hospital, etc., with the date, completes each case so far as the field hospital is concerned.

The receiving-ward may lack the skilled attendance of a surgeon, and the hospital steward must exercise his skill and judgment in therapeutics and minor surgery. Shock must be combated by artificial heat, hot coffee, beef-tea, ammonia, or other stimulants. Pain must be mitigated by morphia, by the mouth or hypodermically; in severe cases by anæsthetics. Hemorrhage must be watched for and promptly checked until the surgeon finds time for its permanent arrest. The order in which patients are sent to the operating-room must be determined. Hemorrhagic cases must go first; cases in shock or collapse must be given time to rally; cases requiring an anæsthetic may alternate with milder ones, to give time for the administration. The anæsthetic will be given in the ward, as a view of the operating-table may unnerve the patient and aggravate the unpleasant effects of the drug.

In the permanent ward, as the cases are received from the operating-room, we aim to place them as we would have them should our hospital become permanent indeed, for wounded men must not be moved about needlessly. Prisoners requiring a guard will be placed together. Severe cases, not admitting of further transportation, will be consolidated, not alone for convenience of nursing, but because they will be disheartened at seeing other cases selected from the same tent to go to the rear; then, should you be compelled to abandon the location, fewer men and fewer tents will need be left behind. Here each man's record must be verified and completed. Everything must be kept well closed up, ready to move at a moment's notice. This constant state of preparation for all contingencies is the proper remedy for the uncertainties of the situation, and will prevent that hurry which soon passes through confusion to panic. For the wounded, the battle is over; and all rumors from the front must be rigorously excluded from the ward, as provocative of excitement and worry.

In a few hours after the battle the last of the wounded will have been brought in, cared for, and sent away to a permanent hospital; instruments will be cleaned, dried, and restored to the cases; dressings and other property repacked; surplus tentage returned to the distributing centre; supernumerary ambulances sent to rejoin the central train; and the field hospital is again a camp hospital, ready to take its place behind the marching column at the trumpet call.

The Ambulance Station.—As soon as the field hospital is located, a steward will go forward with the ambulances and bearers toward the fighting line. The hospital is marked by a flag; guidons must be planted along the roads leading to it. Study by the way all lanes and cross roads, to determine the shortest and best routes for the return of the ambulances. Remove obstructions, repair bridges, fill dangerous ruts, and grade bad crossings, as you go along. Choose a route not likely to be obstructed by troops or trains, screened from the enemy by hills or timber. Note the relation of prominent landmarks to the field hospital, and the roads leading to it, that short and definite directions may be given from afar.

The service of the ambulance mules is very important; and their safety must be considered in locating the ambulance station. The limit of safety is generally fixed at about a thousand yards from the line of battle; but the nearer the approach, the greater will be the effective capacity of the bearers, the more rapidly can the wounded be removed from the field. A wood, a hill, a railway cut, or a ravine, may justify a much nearer approach to the scene of action. These things must be determined in a single topographical glance. The spot chosen must be a little off the main road, which must not be obstructed; must afford space for ambulances to pass in and out without collision, and without short turns, for drivers must have a free headway to bring startled mules under control. Uneven ground must be avoided or remedied; the question is not only of broken vehicles, but of increased suffering for wounded men. A hospital flag must plainly advertise our business to friend and foe, and guidons, so planted as to be visible from the entire field, will help wounded men to find the ambulance station. Shelter here will rarely be required; but should there be delay in the ambulance service, shelter tents or blankets can be hung as awnings to give protection from sun or rain. A fire may be started and preparation made to serve hot soup, tea, and coffee. A supply of good water near at hand is an advantage, but is not essential, as every ambulance keg will come filled from the field hospital.

A medical officer may be on duty at the ambulance station, or all the duties may devolve upon the steward. The name, rank, company, regiment, and probable diagnosis of each case brought by the bearers, or coming in alone, must be entered in a suitably ruled book, and on a card to be attached to the patient. The temporary dressings applied on the field must be inspected and readjusted or others substituted, as may be required. Cases in danger from hemorrhage must receive particular attention and be emphasized by a strip of red cloth. Shock must be palliated by hot drinks, ammonia, or other stimulants, care being exercised to avoid excess, always remembering that whiskey is not a panacea, and that stimulants increase the liability to hemorrhage. Pain may be mitigated by narcotics, the dose to be fixed by the Pharmacopœia, and not by the emphasis of the patient's groans. Narcotics will only be given for present pain, and not in anticipation. Many cases will be able to walk to the field hospital, and severe cases have the first claim upon the ambulances. With a broken arm supported in a sling and bound to the trunk, or with a properly bandaged flesh-wound, with a hospital ticket to show the provost guard, no man will care to linger in a spot affording so little luxury or safety, and small parties may be started on foot for the field hospital. Two privates of the hospital corps will furnish sufficient assistance at the ambulance station; if there be more, they may be held as a reserve, to go to the front with the litters as required.

The First Dressing Station.—The purpose of a hospital corps is to take the unfortunate where they fall on the battlefield, and transport them speedily and safely to the quietude and security of a hospital, far in rear, where they can be put under the most favorable conditions for speedy recovery. As the proverb says, a good beginning is half done, and the first dressing station is the place of beginning. Here, amid the din, the turmoil, and the excitement of battle, the attention of the hospital corps must be concentrated upon its own work. With the speed of systematic order, without disorderly haste, each case must have the benefit of cool judgment and skill from the very beginning. This can only be attained by a careful previous training of the men. A glance will tell that a man is dead, but it must be an educated glance, and without a previous caution the men will waste valuable time and leave men to perish from lack of attention, while they are bringing corpses to the dressing station. They must learn to recognize the presence and know the meaning of jetting arterial blood; a few minutes may make the difference between life and death; and it is clearly useless to start for the dressing station if their charge will be dead when they get there. They must learn to slit the clothing with the knife, and, having exposed the wound, to check the ebbing life-blood by direct pressure or by the tourniquet. They must have in mind the evil potentialities of the sharp fragments of a splintered bone, and learn to confine them within limits by such splint material as they have at hand, to secure immobility of the injured limb by binding it to its uninjured mate or to the trunk. They can protect open wounds from further harm by a fold of antiseptic gauze secured by a bandage. The aim of the first dressing station is to fit men for the journey of two or three miles to the field hospital. With intelligent bearers, under the supervision of acting hospital stewards, this work will be so thoroughly done where the man falls that the duty at intermediate points will be of inspection and verification only. Patients still able to walk, will come direct to the dressing station and receive attention there. Before beginning the thousand-yard journey to the ambulance station, as a rule, every case should be inspected and receive a hospital ticket as evidence that this has been done; otherwise uninjured men might straggle to the rear. No matter how slight the injury, no wounded man will be returned to the ranks. The sight of his own blood unnerves a man; he may be a good soldier to-morrow, he is useless in the line to-day. At the ambulance station or the field hospital he can replace a hospital corps private, who can be sent forward for duty with the litters. After every battle there is a list with the uncertain record "missing;" and anxious friends turn to the records of the medical department, which should begin at the first dressing station.

After a continuous peace of twenty-seven years, it is useless to try to follow the duties of the hospital steward through all the intricacies of field service in war. The survivors from our last great struggle are old men now; and the everyday problems, the little perplexities and vexations of that great period have passed from their memories; like the discordant note in distant music, these things have been left behind. The elements already discussed are raised above the humdrum of life: these seemingly petty details assume a vital importance when we consider that, from this starting-point the younger generation must go forward to meet the great problems of the future. We live not for to-day, but patiently strive to perfect our methods in expectation of the moment when Father Time shall change the slide in his dissolving views, when these minor pictures shall fade away, and we shall stand face to face with the grander panorama of a Nation in Arms. The magnitude of the picture will not appal us; for in it we will recognize—as old friends—familiar elements, combined in familiar atoms, multiplied many fold, but ever the same. The steward's work will be simplified; for in this increase of work there must be a division of labor. If he keep the records, it will be without interruption from kitchen or ward; if in charge of the kitchen, he can give it his en-

tire attention; the perfection of his methods will stand out in bold relief; he will be glad that he learned to avoid errors on a smaller scale, for what he learned to save as pennies will be dollars in the larger transactions; his tables, laden with delicacies, will tell the story of long and careful preparation. In immediate charge of the sick, in a large general hospital, in church or schoolhouse, on cars or steamboats, or in tents on the hillside, the ward of the old post hospital with its annexes will forever remain the unit of measure, the model and the type. Each oscillation of the kaleidoscope will produce a pleasing combination, for the beauty of each picture will be derived from the perfection of the same familiar fragments.

The advent of war will bring higher duties; for the increased work there will be a multitude of willing but untrained hands; with a perfect knowledge of details, with long experience in the study of men, the hospital steward will stand forth as a teacher, with a far-reaching influence for good.

Art is long, and time is fleeting, and no man can hope to say, in one short work, the hundredth part of what might well be said on any subject. The chief object of book or treatise is to make men think; and, if this little work is laid down, not only with a knowledge of what has been said, but with a consciousness of dozens of other things that might have been said in the same connection, if it incites to meditation, to more thorough preparation, it is a success—its highest aim has been accomplished.

George W. Adair.

HOUSE PLUMBING, GENERAL PRINCIPLES OF.

During the last six years considerable progress has been made in the practice of plumbing toward the ideal outlined in the HANDBOOK in 1886. Greater simplicity in piping, and more science in the construction of the fixtures, are the most marked features of this progress. Several cities and towns have modified their plumbing ordinances by striking out the requirement for special trap ventilation called "back venting," and architects, builders, and plumbers generally are becoming more convinced of the uselessness and danger of such a requirement.

The importance of constructing all fixtures on the principle of the "flush tank" is becoming widely recognized, and we rarely find to-day in first-class plumbing work fixtures with the diminutive outlets almost universal ten years ago. The waste pipes are now thoroughly scoured at each discharge of the wide-mouthed fixtures now in use, and ample ventilation is effected throughout the entire drainage system by the discharges, as well as by the thorough ventilation of all the main stacks of piping at both top and bottom. Mechanical seals for trapping are fast disappearing, and are now rarely seen in good work. People have become convinced that balls and valves in traps increase the complication, retard the outflow, and add absolutely nothing to the security of the seal. A sound water seal has been shown to afford perfect safety, and, moreover, no other kind of seal is practicable in water-closet traps. Hence the simple "antisiphonic" water seal trap is becoming exclusively used for all kinds of fixtures.

The sanitary rule of setting all fixtures "open" has become fashionable. Traps and waste pipes are neatly and solidly set, and handsomely polished or nickel-plated. They are becoming each year more frankly recognized by architects as legitimate subjects for artistic treatment. Scientifically constructed and beautifully decorated fixtures, set with highly finished open piping, are among the "show" features of a well-appointed mansion to-day. It is the rule now to admit light and air everywhere under the fixtures, where ten years ago it was the exception.

The quick flushing sink for kitchens and pantries described in the HANDBOOK has been greatly improved within the last few years, and is now entirely automatic in its action. It affords, perhaps, the best illustration of what can be done by plumbing fixtures toward scouring out the waste pipes by powerful water flushing.

Figs. 310 and 311 represent the perfected sink in section and in perspective view. The sink is discharged by means of a self-acting siphon, and a vertical strainer is interposed between the flush-pot and its siphon. The short arm of the siphon is trapped with a seal-retaining

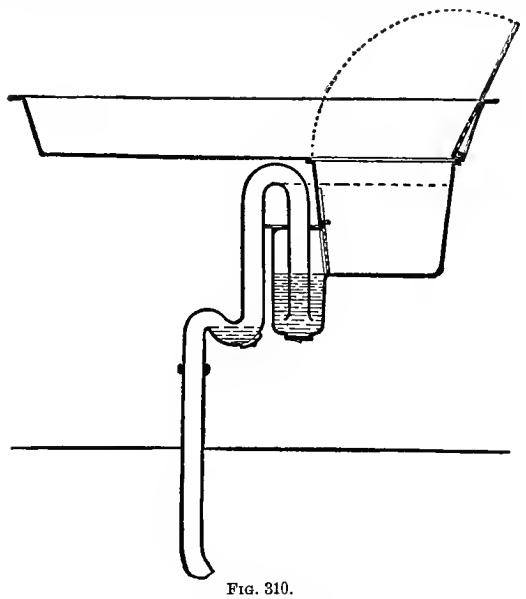

FIG. 310.

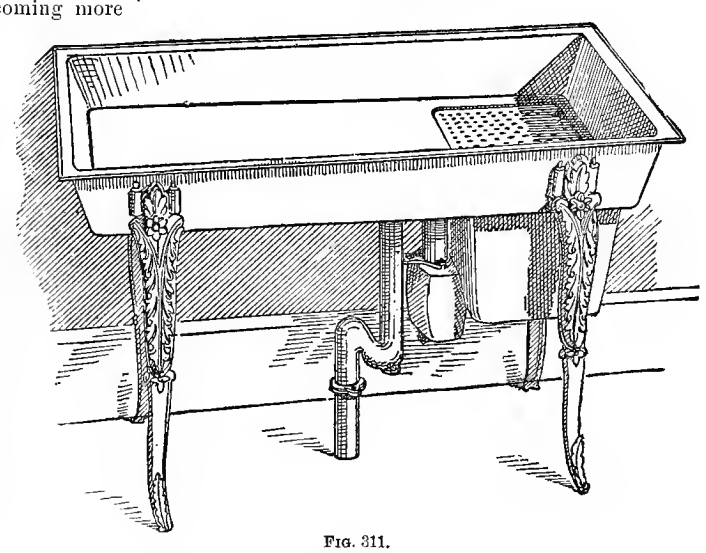

FIG. 311.

trap just behind the vertical strainer. This strainer slides up and down in a groove to give access to the trap when desired, but closes again automatically by its own weight as soon as released. It has been assumed as an indispensable condition in the design of the apparatus, that absolutely nothing should be dependent upon the intelligence or care of the servant, and that by no possibility could the waste passages become clogged, either by accident or by design.

Clean-out openings are provided at the trap and weir-chamber, and give access to every part of the waste sys-

tem. No bones and solid refuse can be scraped into the discharge outlet and dropped into the waste pipe, because this pipe ascends instead of descends at the outlet, and should the top be clogged it will simply cause the water to cease to flow out until the obstruction is removed, which can easily be done by simply raising the lower strainer and lifting out the obstruction by hand.

The operation of this apparatus is as follows: The sink is used in the ordinary manner until the flush-pot fills to the height of the siphon overflow. When this point has been reached the next discharge of a quart or two of water suddenly emptied from the washing-pan or drawn from the faucet, charges the siphon and causes the entire contents of the flush-pot to rush out through the waste passages, filling them "full bore" and scouring them from end to end. The solid matter and large lumps of grease will be left on the bottom of the flush-pot, and must be removed by the servant in the proper manner, inasmuch as they cannot possibly be removed in any other manner.

The simple standpipe overflow basin and bath-tub, and the siphon "jet" water-closet described in the HANDBOOK as lately introduced improvements in plumbing, have now come into very general and constantly increasing use, and in one form or another are recommended by every dealer in plumbing fixtures as embodying the correct principles of construction.

J. Pickering Putnam.

HYDRACETIN (Acetyl-phenyl-hydrazine). A chemical compound of hydrazine, H_2NNH_2, in which two hydrogen atoms are replaced by phenyl and acetyl groups. Its formula is C_6H_5 HNNH CH_3CO. It may be prepared by mixing one part of anhydrous acetic acid with two parts of phenyl hydrazine; the mass becomes hot, and on cooling deposits crystals of hydracetin. *Pyrodin* of commerce is hydracetin mixed with three parts of sugar. It was introduced by Dr. Dreschfield, of Manchester, England, in 1888. Hydracetin is a white crystalline powder, without taste or odor. Soluble in water, 1 part in 50, more so in hot water; very soluble in alcohol. Dose, one-sixth to one-half grain.

It possesses powerful antipyretic properties, and was recommended for typhoid fever, rheumatic fever, and phthisis. The temperature begins to fall in half an hour, and the lowest point is reached in two hours. The effect is not of long duration, and the fever begins to rise again in a few hours. In acute rheumatic fever it appears to have had the best effects, the painful joints being also relieved. It also possesses analgesic properties, and has been used to relieve the pains of locomotor ataxia, neuralgia, and muscular rheumatism, with marked success.

Its employment, however, is negatived by its toxic action. It is a very decided blood-poison, exerting a destructive action on the corpuscles, and hæmoglobinuria is produced. It gives rise to depression, coldness of extremities, sweating, and weakened pulse and respiration. It is generally conceded that it must be used with care, not more than two grains being given during the day, and it should not be continued for more than three days in succession. Guttman, who early reported its value as an antipyretic, and carefully studied its action, advises one and one-half grain a day in divided doses. If the antipyretic action is wanted, the second dose should be given an hour after the first; if for rheumatism or neuralgia, one dose should be given in the morning, the other in the evening.

Hydracetin is also employed as a local remedy for psoriasis, its value in this disease depending upon its reducing power. It is employed as an ointment of pyrodin in the strength of one part in ten. It has failed to meet with approval, as it is not equal to pyrogallol and chrysarobin, and if applied externally may produce toxic symptoms. A case is reported where a ten per cent. ointment, applied to a third of the surface of the body, produced jaundice, hæmoglobinuria, and the usual poisonous symptoms within ten days. *Beaumont Small.*

HYDRASTIS CANADENSIS (Golden Seal). Although not at all a new remedy, its hæmostatic properties have received a great deal of attention during the past few years, particularly in Europe. Attention was directed to it in Germany in 1883, by Dr. Schatz, at a meeting of the Association of Physicians and Naturalists. He described it as an American remedy of decided value, and reported strongly in its favor for the treatment of chronic hyperæmia, and chronic inflammation of the internal genital organs attended by losses of blood. Since this introduction it has been extensively employed with very general satisfaction. In menorrhagia and metrorrhagia without organic disease, as well as in hemorrhages associated with metritis, endometritis, and other structural changes, it is said to check the flow more rapidly than any other remedy. In the hemorrhages occurring at the menopause, and the excessive menstruation of young girls in which the tissues are relaxed and congested, it has proved itself particularly useful. It also relieves all conditions of congestion of the pelvic organs, ovarian pain, dysmenorrhœa, and other distressing symptoms arising from this cause. Its action when the flow is due to myomata appears uncertain, some observers claiming for it decided curative powers, while others have failed to secure any benefit. It has been used in obstetric practice without producing any ill effects. Bossi, of Genoa,[1] gives the result of sixty-four cases in which he employed the fluid extract in such cases. He gave from one hundred to two hundred minims daily, in divided doses, and found that it had "a constant, curative, and prophylactic hæmostatic action on the uterus during pregnancy, labor, and the puerperium, without any ecbolic effect or modification of the uterine contractions." He found it more beneficial than ergot in the flooding of labor and in post-partum hemorrhages, and he trusted to it as a prophylactic for hemorrhages at all periods. Notwithstanding this very decided statement regarding its ecbolic properties, it should be administered with great caution during pregnancy. Cases are reported[2] in which it has exerted a very powerful action on the uterine muscular tissue and induced abortion. Dr. Falk[4] in his experiments with hydrastinine was not able to arrive at any conclusion, but thought it probable that it did possess an ecbolic action.

The hæmostatic properties of hydrastis are due to a constricting action on the arterioles, and this effect seems particularly directed to the vessels of the uterine mucous membrane. Numerous experiments have been made to determine the physiological action of the drug, and among the more recent is a very thorough study of the alkaloid made by Dr. Cerna,[3] of Philadelphia. The following are some of his more important conclusions: Hydrastine is poisonous to animals, the minimum lethal dose in dogs being 0.50 gramme for every kilogramme of the body weight; it kills by failure of respiration. In small doses it appears to have a stimulating effect on the muscular tissue; toxic quantities, however, destroy the irritability of the muscular tissue; on the nervous system it resembles strychnine in its action, increasing reflex activity by stimulating the spinal cord; in larger quantities it produces convulsions, and lastly paralysis; on the circulation, its effect is to diminish the number and increase the volume of the cardiac beats, by an action upon the heart-muscle and the intra-cardiac ganglia; in minute, medium, and poisonous doses it invariably causes a fall in the blood-pressure; in lethal doses this continues until death occurs, while in smaller and medium doses the pressure gradually rises again, but never above the normal point. This lowering is due to a direct action on the heart, and through a paralyzing influence exercised on the vaso-motor system, acting through the central nervous ganglia.

Although the active principles obtained from the plant have been extensively employed, the tincture and fluid extract still sustain their reputation and are preferred by many. Twenty or thirty minims of the tincture, or twenty minims of the fluid extract, repeated four or five times a day, will generally secure all the virtues of the plant.

Two alkaloids have long been known, hydrastine and beberine, and a third termed xantho-puccin has recently been described, but it has not been definitely separated, and its identity remains a matter of dispute.

Hydrastine possesses all the hæmostatic properties of the plant. Its salt, the hydrochlorate, is usually employed. It is a crystalline white or faintly-yellow salt, soluble in water and having an extremely bitter taste. It is employed in doses of from half a grain to five grains, in the same conditions and with the same objects in view as when the preparations of the crude drug are given.

The alkaloid *beberine* is not present in large quantities, and is generally obtained from *beberis vulgaris*, in which plant it is present in large quantities. It is devoid of any hæmostatic properties, and is employed as a tonic and alterative. It is a bitter orange-yellow crystalline powder. *Hydrastin* is an eclectic remedy consisting chiefly of beberine and extractive matter. It is used for many of the purposes for which the alkaloid is employed, and as a cholagogue, stomachic, and tonic. It is a bright-yellow powder.

The latest product, and what is looked upon as the final active principle, is *hydrastinine*. It is a product of the oxidation of hydrastine which breaks up into hydrastinine and opianic acid. Hydrastinine hydrochloras, the salt employed, is a pale-yellow crystalline powder, hygroscopic and soluble in its own weight of water. The dose is very much less than that of hydrastine, being from half a grain to one and a half grain. This substance is said to possess all the medicinal properties of the plant, and is used in all the disorders for which the latter has proved beneficial. The reports of its use are very satisfactory. It is said to act very rapidly, producing its effect almost immediately when administered by subcutaneous injection, while the preparation of the root requires several days' administration before any decisive effect is produced. Dr. Falk[4] has used it in all forms of uterine hemorrhage with very great success; in menorrhagia he obtained the best results by commencing the treatment six or eight days before the expected flow. He gives during this time a daily hypodermic injection of three-quarters of a grain of the hydrochlorate of hydrastinine, and when the flow has begun he doubles the dose. He uses a ten per cent. solution in distilled water. No advantage or disadvantage arises from larger doses. Other reports[5] are equally favorable: twenty-six out of forty-eight cases of hemorrhage were checked within twenty-four or thirty-six hours, and of twenty-seven cases it exerted a decidedly beneficial action in twenty-four. It was administered in capsules or pearls, each containing three-fifths of a grain, three or four being given daily. No unfavorable symptoms followed its use.

Its vaso-constrictive action has suggested the use of hydrastinine in epilepsy.[6] Experiment on animals with two-thirds of a grain per kilogramme, distinctly diminished the excitability of the cerebral cortex, and moderated or prevented artificially induced epilepsy. These observations led to its use in six cases of epilepsy, in doses of from one-quarter of a grain to one or two grains per day. In four of the cases the attacks decreased, both in frequency and intensity; in the other two not much benefit was noticed.

In addition to the hæmostatic properties, hydrastis also exerts a beneficial effect on the mucous membrane of the digestive tract. It has been used with success in atonic dyspepsia, and habitual constipation due to torpid liver; and in the debility arising from the drain of the bleedings it acts as a tonic, resembling quinine in its action.

Its local action is also important, its alterative and astringent properties having long been utilized. It is used as a lotion or injection in leucorrhœa, purulent vaginal discharges, erosions of the uterus, and gonorrhœa. Its local application has also been beneficial in pharyngitis. *Beaumont Small.*

HYDROFLUORIC ACID. The employment of inhalations of this gas has been suggested by Dr. Dujardin-Beaumetz as a means of treating tuberculosis of the lungs. Knowing its very powerful antiseptic and bactericidal properties, and it having been demonstrated that a 1 to 3,000 solution was destructive to the tubercle bacilli, he instituted a series of experiments, and found that animals could live without inconvenience in an atmosphere containing one part of hydrofluoric acid to 1,555 of air. Inquiry among the employees of glass-works also showed that the vapors in no way acted injuriously on the workmen, and those who were afflicted with pulmonary affection were benefited by employment in the works. For the purpose of applying this treatment the patient is placed in an air-tight compartment in which the atmosphere has been impregnated with the gas. One grain of the pure acid may be vaporized in a room of the capacity of twenty-two cubic metres, which gives the proportion of 1 to 25,000; or, the room may be filled with air that has been forced through a solution containing fifty per cent. of the gas. The patient is placed in the room for one hour daily, the period being gradually prolonged. The results of this treatment are varied: in some instances very favorable results were obtained, in others it proved irritating and increased the pulmonary trouble. Experience has shown that asthmatic and emphysematous patients, and those subject to hæmoptysis should not be subjected to the treatment.

Inhalations have also been applied to other zymotic diseases. In diphtheria it has been used, the air of the room being impregnated with the gas obtained by vaporizing the acid, or by the action of sulphuric acid on fluor-spar.

In whooping-cough it is reported to have a very decided effect. One tablespoonful of the acid is put in about one quart of water in an inhaler, and used every second day. Four or five inhalations are said to check the paroxysms, and the cough that remains may be treated as an ordinary catarrhal affection.

The ordinary acid of commerce is impure and requires to be redistilled for medicinal purposes. It is an aqueous solution of about thirty per cent. of the gas, from which copious white suffocating fumes are evolved. It requires to be kept in leaden or gutta-percha vessels, on account of its corroding action on glass.

The salts of hydrofluoric acid have been utilized for their antiseptic properties, the fluoride of sodium being the most suitable. It is quite unirritating, and is recommended for use where bichloride of mercury cannot be employed. Experiments have shown that a 1 to 350 solution prevents the growth of the yeast fungus, and pathogenic and non-pathogenic microbes. Solutions of the strength of 1 to 3,000 may be used for ordinary antiseptic purposes. *Beaumont Small.*

HYDROGEN PEROXIDE. There has been an extraordinary revival of this compound during the past few years. No new method of utilizing its many virtues has been discovered, nothing new has been added to its medicinal properties, and yet, after an interval of more than thirty years, its value is suddenly recognized by the profession and it becomes "the necessary peroxide of hydrogen." It is difficult to trace the cause of this sudden prominence, but in all probability we have to thank the enterprise of the manufacturers for bringing it to the notice of the physician and the surgeon.

Discovered in 1818 by Baron Thénard, it remained almost unknown until Dr. B. W. Richardson instituted a series of experiments, to consider the possibility of utilizing it in the treatment of disease, and communicated the result of his work to the Medical Society of London in 1860 and 1862. These papers formed a very exhaustive treatise and introduced the subject in almost as thorough a manner as we know it at the present day, although the presence of germs and the rôle they play in disease was not known at that time. The following is Dr. Richardson's *résumé* of his papers. In the paper of 1860 he advanced that, (*a*) the peroxide quickens oxidation, increases secretion, arterializes blood, and hastens the decomposi-

tion of decomposing animal tissue; (*b*) in combination with blood it restores the power of muscles just dead to contract, and yet calms muscular irritability; (*c*) that it promises valuable aid in a large number of cases of disease; (*d*) that in instances of poisoning by narcotics and the alkaloids it might with advantage be introduced in the blood by transfusion or injection; (*e*) that in tetanus it affords a most rational treatment, since tetanic rigidity is lost by its presence in muscle; (*f*) that in typhus, in which death takes place from what I designated as asphyxia commencing in the blood, it might be employed with good effect as an oxygenator; (*g*) that it ought to prove useful both as an internal and an external remedy in the treatment of cancer. In the paper of 1862 the following were his conclusions: (*a*) that in diabetes the peroxide reduces the specific gravity of the urine, while it rather increases the quantity; (*b*) that in chronic and subacute rheumatism it affords relief; (*c*) that in valvular disease of the heart with pulmonary congestion it gives relief to the dyspnœa; (*d*) that in mesenteric disease and in jaundice it causes an improvement in the digestion; (*e*) that in pertussis its effect for good is very remarkable, since it cuts short the paroxysms of cough, and seems decidedly to shorten the period of the disease; (*f*) that in chronic bronchitis it lessens the dyspnœa and renders the expectorated matter less tenacious; (*g*) that in chronic laryngitis it gives pain on being swallowed, and does not appear to be useful; (*h*) that in anæmia it does not of itself render a service, but favors the good effect of iron; (*i*) that in the first stage of phthisis it causes improvement in the digestion, and in the later stages gives unquestionable, and even wonderful, relief to breathlessness and oppression, acting, in fact, like an opiate without producing narcotism, and assisting oxidation; (*j*) that it produces a modified salivation, and might be a good substitute for mercury and the iodides in the treatment of syphilis.

In these papers, although noticing the disinfectant properties, the author did not emphasize their importance, but in an address to the British Medical Association, in 1865, the local employment of the remedy and its disinfectant property were particularly dwelt upon. On this occasion he introduced its use as a spray, and recommended it as a disinfectant for sick-rooms in which patients were suffering from infectious disease, for fetid and ulcerated surfaces, and for the treatment of diphtheria, syphilitic ulcerations of the throat, and gangrene.

Until quite recently there appears to have been but little advantage taken of these important communications. From time to time an occasional paper would appear, and with the advance of knowledge in the field of bacteriology its germicidal properties were demonstrated, but the applications of these properties to the treatment of disease were wholly disregarded. The revival of its use may be said to date from a paper by Dr. E. R. Squibb, of Brooklyn, published in Gaillard's *Medical Journal* for March, 1889, in which he pointed out its valuable properties and advocated its use in diphtheria. There had been occasional communications before this, but they had not attracted the attention of the medical authorities, or influenced the profession to any extent. Numerous papers and reports of cases treated with the peroxide followed, but it was not established as a remedy in surgical practice until Dr. R. T. Morris, at the meeting of the American Medical Association, in 1890, described its usefulness wherever there was formation of pus.

Very little is known of the chemical constitution of hydrogen dioxide. It has the formula H_2O_2, and is described as water combined with an additional atom of oxygen, but what this combination is has not been determined. Richardson considered it identical with ozone, and this view is very generally accepted; it responds to the same tests, and it has been found that water saturated with as many volumes of oxygen in no way resembles the solution of the peroxide, and the action of the two is very different. In using the peroxide it is possible to secure either the ozonic action or the action of simple oxygen; if the solution or spray is used ozone is the active ingredient, but if the peroxide is decomposed the gas that is evolved is no longer ozonic but simple oxygen gas.

The therapeutic value of the peroxide depends upon its instability, and the decomposition that takes place when it comes in contact with certain substances. It is compatible with the mineral acids, alcohol, alcoholic solutions of the alkaloids, alcohol combined with ether, amyl nitrite, glycerine, tannin, and is not decomposed by healthy living tissue, or if decomposed by other substances, exerts on it no injurious influence; but in the presence of every form of germ life, decaying organic matter, pus, or abnormal secretion, it is instantly decomposed and the liberated "ozonic" oxygen attacks and destroys such substances. Its action is perfectly simple and uninjurious, it cleanses the part of all impurities, and acts as a mild stimulant to granulation tissue; it does not cause pain, except in a slight degree when applied to the delicate mucous membranes of the nose, conjunctiva and urethra.

Possessed of this bactericidal action and the property of destroying albuminoid discharges and necrosed tissue, its value in many surgical diseases is readily understood. Applied to ulcers, abscesses, or any secreting surface, it destroys all foreign matter and leaves a clean healthy surface ready for immediate repair. A daily application of the fifteen-volume solution, and dressing with borated lint or any simple dressing, will secure a healthy and rapidly healing surface. In abscess cavities the same treatment may be adopted after evacuation, and Morris states that it is possible to open an abscess of the breast, sterilize it, and destroy the pus, and have perfect recovery, under one dressing. Where there is a sinus or where the abscess is deep and burrowing, it is better to inject slowly and gradually, allowing the first portion to cease effervescing before a further injection is made. In some instances, where the sinus is not deep, it may be desirable to inject freely, the distention that follows allowing the fluid to permeate more thoroughly into the numerous recesses that may be present. For sloughing and gangrenous conditions of cancerous disease it is invaluable to the surgeon and to the patient. It rapidly disinfects the part and removes the offensive odor, and its hæmostatic properties check any dangerous hemorrhage that may follow the removal of sloughing tissue.

For inflamed mucous surfaces, where pus is freely secreted, it may be used with much advantage, particularly if the discharges are foul and offensive. In conjunctivitis, ozæna, ear troubles, cystitis, vaginitis, and gonorrhœa, the parts are to be first washed and a solution of fifteen volumes diluted with eight or ten parts of distilled water applied freely. In these cases it will sometimes be found necessary to use cocaine to allay any sensitiveness. In washing out the cavity of the bladder a double catheter should be used to allow the liberated oxygen to escape.

It has lately been used in the treatment of empyema. Cases are reported in which the pleural cavity was washed with the peroxide, followed by a borated solution. The advantage derived from the peroxide in all cases was very decided, recovery being rapid and unaccompanied by any unfavorable symptom. In poisonous snake-bites and the bites of rabid animals, it is recommended as an antidote, and has been used with good effect to counteract the painful effects of rhus poisoning.

Its powerful local action makes it a very valuable application in diphtheria, and this is one of the most important uses of this compound. It proves very efficient in destroying and removing the diphtheritic membrane and counteracting the ptomaïnes that may be formed.

The frequency and strength of the application to a great extent depends on the character of the disease. Two or three applications may be sufficient, but if the membrane is extensive and interferes with respiration, the solution can be used every hour with benefit. Spraying or gargling should always be adopted. The fifteen-volume solution is used in its full strength if the case is urgent, but the solution diluted with three or four parts of water will generally be sufficiently strong. Reports point to its very great service, and it is rapidly becoming the one topical application that is supplanting all others.

In all forms of diphtheritic inflammation it is equally efficient, as either in the nose or in the larynx the spray readily reaches the site of the disease. In addition to its beneficial local action, the inhalation of the liberated oxygen undoubtedly is of benefit, particularly in the severe cases in which the oxidation of the blood has been interfered with, and the patient is in a condition of cyanosis.

The internal administration of the peroxide is as important as its topical use. In giving it we are giving oxygen, and, as in its local application, it is the supply of free oxygen upon which its beneficial action depends. Within the intestinal tract, as well as on the surface of the body, its disinfectant and bactericidal properties are taken advantage of. In thrush, aphthous states of the mucous membrane of the mouth, and all such unhealthy conditions, it acts quickly and beneficially. In chronic gastritis, gastric ulceration, and all catarrhal disorders accompanied by fermentation and flatulent indigestion, its use checks the abnormal fermentation and restores the disturbed function. Under its influence the general acidity of the gastric juice and the proportion of free hydrochloric acid are increased, and the digestive power markedly improved. In the forms of dyspepsia accompanied by hyperacidity the administration of the peroxide causes an aggravation of all the symptoms. One drachm of the fifteen-volume solution, diluted, three times a day before meals, has proved a sufficient dose. For disturbances of the lower bowel and rectum it may be administered as an enema. Richardson used one ounce to a pint of water and injected it through an O'Beirne tube. In typhoid fever it has been used in this way and administered by the mouth. One ounce may be diluted with one pint of water and taken during the day as a beverage. Richardson used it with favorable results, and Dr. H. F. Wiggin, in the New York *Medical Record*, November 28, 1891, reports a case in which he believed that the peroxide proved of great value. In addition to the above conditions, in which it exerts a local disinfectant action, its power of oxidizing the blood opens up a train of diseases in which it may prove of very decided service. Whether administered by the mouth or inhaled into the lungs, it affords rapid relief in asthma, emphysema, chronic bronchitis, phthisis, heart disease, and in acute pneumonia. Also in poisoning by hydrocyanic acid and the numerous new aniline compounds it should prove of benefit. In pulmonary phthisis it not only relieves dyspnœa and shortness of breath by improving the blood, but also counteracts the night-sweats and fever by neutralizing the ptomaïnes. It is also supposed to act favorably by destroying the bacilli and the purulent infiltrated tissue. In the first stages it possesses a decided remedial action, and Richardson states that it is, of all medicines, the most valuable. This observer also suggested that it might be administered by subpulmonary injection, throwing the solution directly into the lung tissue. He considers that no harm should follow this method, and the oxygen would rapidly diffuse and destroy the tuberculous exudation. In whooping-cough it is said to act almost as a specific, given internally and inhaled. Dose: from ten to eighty minims, three times a day, diluted. Its beneficial action here is due not only to its antiseptic properties, but also to its power of relaxing muscular spasms. Its action is the same in asthma and angina pectoris, and other spasmodic affections. This action described by Richardson leads him to suggest its use in hydrophobia and tetanus. He proposes to inject groups of muscles with the ten-volume solution, using amyl nitrite in combination if necessary.

The property of promoting oxidation in the system has led to its use in diabetes, with beneficial results. The sugar is rapidly diminished, but the amount of urine is increased, this latter effect being characteristic of the peroxide, which increases all the glandular secretions. To overcome this excessive secretion the following combination is used by Dr. Richardson: Codeine, 3 grains; alcohol, 2 drachms; peroxide of hydrogen (10 vols.), 2 fluid ounces; distilled water to make 12 fluid ounces; a tablespoonful to be taken three times a day in a wineglassful of water. Many other observers have obtained the same satisfactory results in this disease.

On account of its stimulating effect on the excreting glands, it is highly extolled by Richardson in the treatment of syphilitic disease, especially in the secondary and tertiary stages. For indolent ulcers, skin lesions, and tertiary deposits its internal administration is very beneficial, particularly if the cachexia is marked. He recommends that it be given in two- to four-drachm doses, three times a day, with infusion of cinchona. The only unfavorable action is a mild form of salivation, which is readily overcome by stopping the medicine. It also increases the action of mercury when given at the same time, much smaller doses of the mercurial salt proving effective.

The evolution of the oxygen and the great expansion that accompanies this physical change, furnish what may be termed its mechanical use. This may be taken advantage of in invagination of the bowel, and may also prove serviceable when sounding the bladder for stone, a small quantity causing a sufficient distention for the purpose. It is also recommended to inject it into a part in which suppuration is suspected. If pus is present the usual reaction occurs and distention follows, into which an incision may be made with facility.

The freedom from toxic action and its unirritating qualities render it a very simple remedy to use. One to two drachms of the fifteen-volume solution, three or four times a day, can be administered, without the fear of any unfavorable symptoms, and will generally prove sufficient to secure all its peculiar effects. It should be freely diluted with water free from any organic matter, and mixed as required. For enemata and for hypodermic injection the solution should always be neutralized with soda.

For sick-rooms its disinfectant and deodorizing properties are best secured by diffusing it as a spray, and hard rubber or glass appliances only should be used. For spraying the throat the solution may be medicated with tannin, quinine, morphine, or any of the alkaloids soluble in alcohol.

The subcutaneous injection is indicated only when an immediate and rapid supply of oxygen to the tissues is wished for, as in asphyxia from drowning, hanging, or in chloroform poisoning, or poisoning from any narcotic. In extreme cases of chloroform poisoning Dr. Richardson suggests that deep subpulmonary injections might be made, throwing the peroxide directly into the pulmonary tissue of each lung. The solutions should be diluted and free from any acid, and of the temperature of the body. No ill effects should follow, as the oxygen is rapidly absorbed, and the small amount of water that remains is harmless.

For inhalation the oxygen is very readily eliminated from the solution, by the aid of permanganate of potash, which also supplies its share of oxygen. A ten per cent. solution of the permanganate added to the peroxide at once decomposes the solution thoroughly. This reaction may be produced in an inhaler and the gas at once utilized, or it may be preserved in balloons and used as required.

The peroxide of commerce is a two or three per cent. solution of true peroxide of hydrogen. Pure anhydrous peroxide of hydrogen is known only as a chemical curiosity, and is described as a colorless, transparent, inodorous liquid, specific gravity 1.45, extremely unstable. When decomposed it yields four hundred and seventy-five times its own bulk of oxygen, leaving behind a little less than one volume of water. The solutions of commerce are designated by the numbers of volumes of the gas that they supply, being five-, ten-, or fifteen-volume solutions, according as they contain a little over one, two, or three per cent. of peroxide of hydrogen. To be exact, a one per cent. solution should supply 4.75 per cent. of oxygen, and a fifteen-volume solution should contain a little more than three per cent. of the peroxide. The pure peroxide is of course undesirable, not only is it not manageable, but it is altogether too strong for any practical use.

The preparation is still the same as that proposed by its discoverer. It may be formed from the peroxides of any of the alkaline earths, but barium is the most suitable. The barium oxide is formed by exposing baryta, heated to redness, to a current of oxygen gas; the resulting salt is then acted upon by hydrochloric acid which releases the oxygen, and this combines with the water to form the peroxide of hydrogen. Fourteen parts of hydrochloric acid are diluted with nine hundred and sixty parts of distilled water, and to this thirteen parts of powdered barium dioxide are added. This gives about a one per cent. solution of the hydrogen dioxide. The barium chloride, which is still in solution, is removed by treating with dilute sulphuric acid, and the chlorine, which remains as hydrochloric acid, is precipitated by sulphate of silver and baryta water. The presence of a small amount of hydrochloric acid is useful in maintaining the stability of the solution, and it is generally present in a slight degree; the amount, however, should be very small. Richardson preferred the addition of dilute phosphoric acid, but the acid produced during its manufacture is the one usually present.

The instability of the peroxide renders the article of commerce of a very indefinite strength. Numerous analyses show that the solutions are far below their nominal strength. Of nine specimens examined by Dr. S. S. Wallian,[1] only two were found to be of the proper strength, and one sample of a ten-volume solution contained one and a half volume only. Dr. H. E. Smith[2] analyzed fifty samples, and found that the highest volumetric strength was only 8.86; eight per cent. of the samples did not contain any hydrogen peroxide whatever, and thirty-six per cent. were decidedly deficient in strength. Dr. E. R. Squibb[3] examined nine samples of the five leading manufacturers' products, and found that only one reached two-thirds of the proper strength, and two samples were less than one-half the stated strength. These results speak for themselves, and when it is remembered that many of the articles that are supplied to the physician have been in the chemist's shop for a prolonged period, with very little care to preserve their properties, there is little wonder that the results obtained from its use are not as favorable as expected.

It is desirable to keep the bottle away from the light and in a cool place, but the decomposition that goes on within the bottle is due to organic matter and other impurities in the solution. A good preparation should remain fairly stable, even when of a high strength. Squibb states that, even when exposed to a summer temperature, it should grow stronger rather than weaker, as the water should evaporate more rapidly than the peroxide decomposes. A solution of peroxide should be bright and clear and free from any deposit or cloudiness, this arising from the oxidized matter thrown down by the decomposition of the peroxide. To prevent this decomposition, free acids are added, but if impurities are present the loss of oxygen still continues.

The strength of the solution may be tested with a standard solution of permanganate of potash. Dissolve 2.832 grammes of potassium permanganate in distilled water sufficient to make 500 c.c. of the solution. Ten c.c. of hydrogen peroxide is then diluted with water to make 100 c.c., and ten c.c. of this is to be tested. A few drops of sulphuric acid are added to acidify the solution, and into it the permanganate solution is to be added, drop by drop, until it begins to color the solution. The number of c.c. used indicates the number of volumes of oxygen present. Another method of testing is to decompose the solution and collect and measure the oxygen evolved.

Ozonic Ether.—At the British Medical Association, in 1865, Dr. Richardson introduced this combination of ether and peroxide of hydrogen. He produced it by agitating a thirty-volume solution of the peroxide with anhydrous ether and adding five per cent. of alcohol. It is soluble in water, is more stable than the solution of peroxide, and may be administered in all the conditions in which the latter is used. The dose is from half to two drachms. As a spray for topical use and to disinfect the atmosphere it is particularly serviceable. In whooping-cough it is very highly praised, as almost a specific remedy; it is used as a spray and the following mixture given: Ozonic ether, three drachms; syrup of Tolu, six drachms; glycerine, four drachms; distilled water, to make six ounces; one-half to two tablespoonfuls for a dose. The ethereal compound also permits of its union with fatty bases for inunction. This is employed in scarlet fever as a disinfecting application, the use of which prevents any poisonous matter from being disseminated, and at the same time is a soothing and emollient application. Richardson also recommends the use of ozonic ether for the production of anæsthesia, the presence of the oxygen preventing any dangers that might arise from partial asphyxia.

Under the name *pyrozone*, there is supplied an ethereal solution of different degrees of strength. In one it is stated that there is as much as one hundred and twenty volumes of oxygen.

Glycozone is another preparation of peroxide of hydrogen, in which glycerine is acted upon by the peroxide under pressure; it is said to supply fifteen volumes of oxygen. The advantage claimed for it is that it is more stable, acts more slowly, and proves more efficient as a dressing for wounds and other surgical purposes.

HYDROPS ARTICULORUM INTERMITTENS. An extremely rare and obscure disease, characterized by periodically returning attacks of swelling of one or more of the larger joints, unaccompanied by fever or any of the usual signs of inflammation.

But thirty-three cases have so far been reported, and of these but three in this country, the two observed by Fridenberg and the one of my own.

There is a remarkable uniformity as regards the symptoms in all the cases, they forming a clinical picture so characteristic and typical as to leave no doubt of the diagnosis in any well-developed case.

The patient notices a slight swelling in one of the larger joints, usually the knee, and perhaps has his attention drawn to it by a feeling of tension, or of discomfort, uneasiness, insecurity, or wabbling in the affected part. This rapidly increases, so that usually, in from twenty-four to thirty-six hours the joint is so swollen as to seriously interfere with, if not to entirely inhibit, the normal functions. In a short time, usually a day or two, the swelling begins to subside, and in from twenty-four to thirty-six hours more it is entirely gone, leaving the joint to all appearance in as perfect and healthy a condition as before. After an interval of perfect freedom the swelling again appears and the same phenomena are repeated, and so on for an indefinite period of time.

There are no premonitory signs or symptoms indicative of the disturbance; the patient may be, and usually is, in his customary good or bad health, as the case may be. During the attacks there are in most cases no signs of constitutional disturbance; the normal functions of the body remain undisturbed. In two cases, those of Bruns and Pletzer, there was a slight rise in the temperature during the initial attacks, but not afterward, while Perrin reports a case in which each attack was preceded by light chills, followed by slight fever ending in perspiration. Simultaneously with this there was a contraction of all the flexors of the upper extremity, also a painful prickling in all the joints of the same limb. A few hours later the swelling began, and with it the above phenomena gradually disappeared.

In most cases there is no acute pain whatever; in some, however, especially when the hip-joints are affected, the pain is quite acute. In these exceptional cases the diagnosis might be difficult at times, as the swelling would be more apt to be overlooked than when the knee was affected. The subjective sensation is more that of tension, insecurity, and wabbling, than that of pain. Examination during the attack shows the swelling to be an

effusion into the joint. When the knee is affected there is the characteristic bulging at the sides of the patella, which, together with the fluctuation and the well-marked floating of the patella, renders the determination of the cause of the enlargement easy. There is no increase in surface temperature, except in one or two instances (Bylicki, Fridenberg), and no flushing or redness of the skin.

The attacks occur with such regularity that in many cases the patients can tell, not only the day, but even the hour when the seizure will begin. As a rule the interval of freedom varies in different cases from eight to fourteen days; thus in thirty out of thirty-nine recorded observations the intervals fell within these limits. The attacks themselves last in the majority of cases from three to five days. Out of twenty-seven observations twenty did not exceed these limits. The longest interval reported was three months, and the duration of the longest individual attack ten days.

As to age, it may be said to be a disease of middle life, most of the cases occurring in patients from twenty to fifty years of age.

Females are about twice as often affected as males. One or both knees are almost invariably involved at some period of the disease. In three of the cases it is not stated which joints were involved; in one other the elbows alone were affected. In all the others the knees were implicated.

Sometimes there is an alternation in the joints affected, one attack being of the knee, the next of the hip, and the third returning again to the knee, and so on. In two of the cases almost all of the joints in the body were involved, even those of the spine and fingers.

A marked peculiarity of the malady is the strong tendency which it shows to spontaneous cessation of the attacks for periods varying from a month to many years, after which it recommences without any assignable cause.

The disease runs a very chronic course, several of the cases lasting from twenty to twenty-five years. Pregnancy in almost all cases puts a stop to the attacks while it lasts. During only one out of nine recorded pregnancies was the patient afflicted. In several the attacks ceased at once at the beginning, and only one reappeared again a few weeks post partum. In no case is there any marked relation to the catameuia reported, though in a few cases the attacks first began at or about the time when menstruation became established.

As to the nature of the affection, there is nothing definitely known. That it is due to vaso-motor disturbance is admitted by everyone who has been fortunate enough to have observed a case; but whether this disturbance is due to micro-organisms, or is a mere neurosis, is at present undetermined. The evidence is but circumstantial in support of either theory. While it is true that several of the cases have occurred in patients subject to various nervous troubles, yet there are many more in persons having absolutely no hereditary tendencies in that direction. Subjective symptoms, as a rule, are more prominent than objective in neurotic diseases, while here we find the objective far more in the foreground.

Pain, as a rule, is only due to the distention of the joint, and there is none of that hyperæsthesia so characteristic of hysterical joints. The argument that galvanization of the medulla has cured one or two patients is not of much force, as both the patients were taking arsenic at the same time, and one of them had had a period of freedom from attacks for four years, at an earlier stage of the disease, following the administration of Fowler's solution. It is a noteworthy fact that almost every case reported cured or improved had taken either quinine or arsenic, or both combined.

Several of the cases had suffered from malarial poisoning at some previous period, and two others at least were from a malarial region. In two cases the spleen is reported as enlarged, and in one of them the swelling subsided simultaneously with the improvement of the patient under the use of quinine and arsenic.

It would take us beyond the scope of this article to enter into the subject of periodicity in disease. There is no satisfactory explanation of it except in those cases dependent on micro-organisms, yet there is scarcely a disease which does not present more or less well-marked traces of it at times. Innumerable instances might be cited, but as there is a separate article on this subject in a preceding volume, to avoid repetition we may refer to it for a discussion of the various theories advanced and for illustrative cases.

In typical cases there is no difficulty in the diagnosis, except that from its very rarity it is apt to be overlooked. Probably most of the cases are called rheumatism at one time or another, yet a very slight examination would show the swelling to be due to an effusion within the joints, and not extra-capsular.

As regards prognosis, the chronicity and liability to remissions and relapses has been already mentioned. In one case the disease finally ran into chronic dropsy of the joint. In one there was some crackling in the joint, and in two a slight thickening of the capsule, noted. In all others, even after many years' duration, there were no signs of chronic changes in the joints.

As would naturally be expected in so obscure an affection, the most diverse methods of treatment have been employed. The natural tendency of the disease to spontaneous remissions makes the proper estimation of any given method very difficult. However, quinine and arsenic enter into almost all reported cures. In my own case, whereas under the old rheumatic treatment the attacks always ran on through a period of several months, since she has tried arsenic and quinine she has found that she can always stop their recurrence after one, or, at most, two attacks. The tendency to relapse remains.

Of seventeen cases reported cured, relieved, or improved, injections of ergotin, electricity, cauterization and fixation, sulphur baths, and injections of carbolic acid, have each one successful result. In all the others quinine and arsenic were the chief remedies employed, so that in any given case these should have the first trial. After these electricity would probably be more serviceable than any of the other proposed remedies.

HYDROXYLAMINE. This compound base exists in the free state only in solution. It is ammonia in which one hydrogen atom is replaced by the hydroxyl group. The formula is NH_2 OH. *Hydroxylamine hydrochloride*, NH_2 OH HCl, forms in colorless crystals resembling chloride of ammonium; it is hygroscopic and very soluble in water, alcohol, and glycerine. It possesses active reducing powers, in consequence of which it has been suggested as a substitute for chrysarobin and other reducing bodies in the treatment of skin diseases. It has been used with success in psoriasis, parasitic affections, and in lupus. It is a powerful poison to all forms of vegetable and animal life, but while proving effective

in destroying the disease for which it is used, it is liable to produce toxic symptoms by its absorption and influence on the hæmoglobin of the blood. The salt should be kept in well-closed bottles in the dark, and when used, a solution of one part in a thousand may be prepared. The diseased part, previously washed with soap, is to be painted from three to five times a day.

Beaumont Small.

HYÈRES AND COSTEBELLE. In addition to the information already given with reference to Hyères (see Vol. III. of the HANDBOOK), the following particulars may be of interest to physicians. The writer's residence at Hyères was too brief to permit personal verification of all that is claimed for this Provençal winter station. But the testimony of Drs. Biden and Cormack, the resident English practitioners, agrees in all principal points. There is certainly no question that the winter at Hyères is very mild, and were it not for the *mistral*, and comparative dulness of the town, Hyères would doubtless be quite as popular as Cannes and Nice. Formerly it was much more so. The table given on the next page is reproduced from the writer's description of Hyères in the *Medical Record*, January 16, 1892, and is due to the courtesy of Dr. Biden, who specially prepared it.

FIG. 312.—View of Hyères Looking North.

SYNOPSIS OF METEOROLOGICAL OBSERVATIONS TAKEN AT HYÈRES.—The shade thermometers are placed in a Stevenson's screen. The screen stands in the open, completely exposed all round, quite away from buildings and walls. If $\frac{1}{100}$ of an inch of rain is measured in the twenty-four hours it is considered a day on which rain has fallen.

In regard to indications and contra-indications, the following opinions will suffice: "The winter climate of Hyères and Costebelle is suitable especially for consumption, chronic bronchitis, asthma, heart disease, and rheumatism: also Bright's disease, gout, incipient paralysis, and the feeble constitution of delicate children. In consumption, obviously, the disease is most amenable in its early stages. Nevertheless, remarkable instances have occurred of relief in advanced cases of a type quite unsuitable to Alpine climates. The occurrence of hemorrhage is not a contra-indication to residence here. For those beyond middle life it is difficult to conceive a more suitable environment than Costebelle offers. The climate of Hyères is less exciting than that of Cannes and Nice" (Dr. Sawtell). "The chief attractions of Hyères are its climate and the beauty of its environs, which render it an agreeable place of winter abode, even for persons in health who do not require the animated movement and recreative resources presented by large towns, and who are in tolerable walking condition. The walks and rides, both on the plain and through the cork-tree woods, by which the hills are for the most part covered, present considerable variety, while from the more elevated positions charming prospects may be enjoyed" (Dr. Edwin Lee). The barometer is high and steady, But on the Riviera, as elsewhere, every winter varies in the rainfall and in the degree of cold; and, therefore, it may happen that the traveller's experience will not agree with stereotyped meteorological tables.

Dr. Cormack says (*The Climatologist*, January 15, 1892) that: "Hyères is admirably suited to cases of phthisis. Should the disease be in its first period when the patient arrives, a complete cure may take place. The same result may be obtained with cases which have arrived at their second period, although the chances are less, but in any case a considerable improvement may be expected. When the disease has passed into the third period, or is too far advanced for any reasonable hopes of recovery to be entertained, life is prolonged for a time.

"All chest complaints and bronchial affections improve under this genial climate. Liver complaints, affections of the kidneys, Bright's disease, diabetes, etc., are all favorably influenced by the warm and equable temperature.

"Gouty and rheumatic cases get on very well here, and generally are much relieved after a winter or two's residence. This is only what would naturally be expected when one bears in mind of what capital importance a dry and warm climate is to such cases, and the great benefit they derive from out-door exercise, for which Hyères offers special facilities, for there is hardly a day upon which an invalid is unable to get out for at least an hour or two, unless the nature of his complaint keeps him confined to his bed.

"Cases of anæmia and asthma also do remarkably well for the same reasons.

"The invalid's day is comprised between the hours of 10 A.M. and 4 P.M. for the warmest months, and 11 A.M. to 3 P.M. when the days are colder. Naturally, special cases have to follow special rules; but no invalids, in any case, should go out until the sun is well risen, nor after sunset, as both before and after sunset the temperature is many degrees below what it marks in the middle of the day; it is specially dangerous for delicate persons and those having weak chests to go out after sunset, for there is invariably a very rapid fall in the thermometer at this time. A most useful precaution for all patients is to be provided with a shawl when passing from the sun into the shade, as the difference of the two temperatures is very considerable. There are certain times, during the mistral, for instance, when invalids do well to keep within doors; more particularly is this the case for those of weak constitution or nervous temperament."

Finally, Drs. Biden and Cormack agreed in assuring the writer that Hyères is a healthy town. There is very little typhoid, no diphtheria or other zymotic diseases, and the foreign colony has nothing to fear, and has had nothing to regret at this delightful winter resort. Anæmia and American neurasthenia should do particularly well there. About the only contra-indication for a winter's residence at Hyères is furnished by recent neuroses, with a tendency to mania.

The water-supply of Hyères and Costebelle is moderately good. The water is very hard, however, and does not agree with everybody. The drainage is quite imperfect, and the cesspools, which are in common use, may become sources of danger.

In the writer's report, already alluded to, Costebelle is thus referred to: From the railway station of Hyères it is but one mile of slightly up-hill wooded road to Costebelle. From the town proper it is two miles in a southerly direction. From Marseilles to Genoa, *i.e.*, along the entire Western Riviera, or "*le littoral*," as the French call it, there are ever-changing and enchanting views. But in all this favored strip of land, so abundantly blessed with blue skies and health-giving sunshine, I have found no prettier views than those which are enjoyed from the Costebelle hill-sides.

Situated on the southern slope of an eminence appropriately named *Mont des Oiseaux*, which effectually protects it from that much-dreaded wind called "mistral," surrounded by forests of aged pines, oaks, and olive-trees, that richly clothe in different shades of green the adjoining hills on the north, east, and west, and with a southerly view over undulating woodlands, stretching out into a picturesque plain that ends abruptly at the Mediterranean Sea a mile below, Costebelle has been happily chosen as a site for a few first-class hotels.

The late Duke of Grafton some years ago found it to be a site without parallel along the whole coast. He built a princely villa and made a road through the pines to serve it. But only within the last ten years has any move been made to provide accommodations for the increasing number of visitors.

In addition to the two older hotels (selected for the Queen of England's residence in the spring of 1892), Costebelle has a third and quite modern hotel, called the Albion, which is in every respect a first-class family residence.

At the Albion good sanitary arrangements were found by the writer, and the other Costebelle hotels have been recently overhauled and made nearly perfect in this respect. *Edmund C. Wendt.*

HYOSCINE. This alkaloid is present in other plants beside *hyoscyamus niger*, having been obtained from *duboisia myoporoides* and *scopola carniolica*. It is supposed to be identical with scopolamine, which is isomeric with cocaine and not with hyoscyamine; it is also identical with duboisine. Hyoscine, $C_{17}H_{23}NO_3$, is a non-crystallizable body, but all its salts form in large, white prismatic crystals, freely soluble in water, insoluble in alcohol and ether. The salts also resemble each other in therapeutic as well as physical properties. The hydrobromate, hydrochlorate, sulphate, and hydriodate are prepared.

As a mydriatic it is rapid, energetic, and brief, but its action is readily maintained. During the administration of the drug its effect on the pupil is an early symptom. Dilatation is said to be more marked with a $\frac{1}{4}$ to $\frac{1}{2}$ per cent. solution than with a one per cent. solution of atropine; it has to be used with caution on account of the readiness with which the system is affected.

Its sedative and hypnotic action has brought it into prominence, during the past few years, as a remedy in cerebral excitement and in the treatment of nervous diseases. In small doses it produces a stimulating action on the nervous centres, but in larger doses it is a powerful sedative. When given until its physiological action is produced, it causes the pupils to dilate, and checks the secretion of the salivary glands and the action of the skin. On the heart it depresses the inhibitory nerves, and causes a weak and accelerated action of the pulse. Some observers have noted in the early stages a slowing of the pulse and an increase in the blood-pressure. It diminishes the irritability of the brain and nerve-centres, lessens to a slight extent the perception of pain, but does not affect tactile sensibility. Its toxic action is shown by the dilated pupil, rapid pulse, relaxed arteries, and redness of the surface, dry, hot skin, rapid breathing, and coma and convulsions.

Hyoscine has largely supplanted morphine in the treatment of acute mania and delirium tremens, in restlessness, and violence in all forms of mental disorders, and in hysteria and epilepsy. Its sedative action is very rapidly produced, and in the majority of cases a calm and refreshing sleep ensues. When pain is the cause of insomnia, it is not of much service. Its action is purely calmative and sedative on the brain, and it should not be administered as a powerful or decided hypnotic; in insomnia it is only applicable in cases in which it arises from central or nervous excitement. In mania, and when there is much excitement, it should be given in full doses of $\frac{1}{60}$ grain by the mouth or $\frac{1}{120}$ to $\frac{1}{100}$ grain hypodermically; a small dose is generally sufficient. When the symptoms are less acute, smaller doses should be given.

Hyoscine has also proved itself very efficient in the treatment of chronic mania and all nervous affections accompanied by mental restlessness; also in nervous diseases characterized by debility and tremors, as in paralysis agitans, disseminated sclerosis, and chronic alcoholism. In these cases the stimulating action of small doses is taken advantage of, and $\frac{1}{200}$ of a grain daily or twice a day is a sufficient dose. Its antispasmodic action is also secured with the same small dose, and it may be used, and with benefit, in chorea, asthma, and other spasmodic troubles of a nervous origin. When cardiac disease is present the use of hyoscine should be avoided or given with great caution, on account of its depressing action on the heart and circulation.

The early physiological effects of the drug are mani-

fested far in advance of dangerous symptoms, but in some cases very severe toxic symptoms have been produced by doses of $\frac{1}{60}$ and $\frac{1}{10}$ grain. Pilocarpine and morphine are physiological antidotes. The former has proved very serviceable and may be administered freely, as much as two grains having been required in a case of delirium tremens in which a comatose condition followed frequent doses of hyoscine.

Beaumont Small.

HYOSCYAMINE. This alkaloid, formerly obtained solely from *hyoscyamus niger*, is now known to be the alkaloid present in many other plants of the order solanaceæ, notably *atropa belladonna*, *datura*, *stramonium*, and *scopola carniolica*. It has recently been obtained from the common lettuce plant, *lactuca sativa*.[1] Professor Ladenburg demonstrated that atropine, daturine, and duboisine are identical with hyoscyamine, both in chemical constitution and physiological action. Any difference is to be found in the molecular arrangement of the constituents, and not in any fundamental change. The terms "atropine" and "hyoscyamine" have been applied to the heavy and light mydriatic alkaloids obtained from the belladonna and henbane plants, the former being the heavy and the latter the light alkaloid. It is now known that both the heavy and light alkaloids may be obtained from either plant, according to the process of manufacture. The light may be converted into the heavy by melting under reduced pressure, or by the addition of caustic soda to its alcoholic solution.[2]

Hyoscyamine, $C_{17}H_{23}NO_3$, occurs in light, silky, snow-white crystals, without odor, soluble in one hundred and twenty parts of water, freely soluble in alcohol, and in acidulated water. There is also an uncrystallized or amorphous hyoscyamine, of a dark-brown extract-like mass, with a strong disagreeable odor. This appears to be a mixture of the various alkaloids and extractive matters. A sulphate, hydrochlorate, hydrobromate, and hydriodate of hyoscyamine are prepared; they are alike in degree of strength and character, forming white, fine crystals very soluble in water. A sulphate and hydrobromate prepared from the amorphous alkaloid are amorphous, deliquescent salts, and less active and certain in their effects.

The therapeutic properties of hyoscyamine resemble those of hyoscine, but since the introduction of the latter alkaloid it has fallen into disfavor. It was found to be less certain in its action, and its use was frequently accompanied by unpleasant symptoms. It is employed as an hypnotic, nerve sedative, and antispasmodic, in mania, restlessness, delirium, insomnia, and all conditions accompanied by mental excitement, also in asthma, chorea, epilepsy, etc.

The dose is somewhat larger than that of hyoscine, $\frac{1}{100}$ to $\frac{1}{10}$ of a grain, which in some cases requires to be increased to $\frac{1}{4}$ grain to obtain the desired action. The presence of the amorphous salts in the market is the source of much of the uncertainty of its action, and the cause of many of the toxic symptoms. The dose of these salts is much larger, being from $\frac{1}{8}$ to 1 grain.

Its mydriatic action is rapid and powerful, but not so manageable as atropine. Cases[3] are reported in which it produced spasms of the ciliary muscle and intense pain and distress; the solution used was $\frac{1}{4}$ grain to the drachm, and relief was obtained by placing in the eye a stronger solution of the same alkaloid. Its toxic action is the same as that of hyoscine, viz., dryness of the throat and mouth, and of the skin, accelerated pulse, dilated vessels, and excitement followed by convulsions and coma.

HYPNAL. It is well known that a mixture of antipyrine and chloral results in the production of an oily fluid, which in time again crystallizes. Dr. Bardet (*Répertoire de Pharmacie*, April 10, 1890) made known the fact that when combined in certain proportions the compound possessed the therapeutic properties of its component parts; to this product he gave the name of hypnal. It may be prepared by mixing a solution of 47 grammes of chloral hydrate in 50 c.c. of distilled water, with a solution of 53 grammes of antipyrine in 50 c.c. of distilled water, pouring into a separating funnel, and drawing off, after an hour, the oily-looking fluid from the aqueous layer. At the end of twenty-four hours the liquid will have solidified to a mass of rhombic crystals.* The salt is colorless, odorless, soluble in five or six parts of water, being less soluble than either chloral hydrate or antipyrine.

Bardet found it very useful as an hypnotic and analgesic. He employed it in twenty-two cases, and found it to produce sleep as readily as chloral hydrate, and where pain was present marked relief was at once secured. He also found it act very beneficially in producing sleep when the cause was a spasmodic cough. It has not the bitter taste nor the disagreeable effect on the stomach of its constituents, and secures its desired effect in comparatively small doses. No ill effects have followed its use, but in some instances where it has failed to produce sleep it has given rise to increased restlessness. It is easily taken by children on account of its freedom from taste.

The dose is from seven to fifteen grains for adults. It may also be given hypodermically in the same quantities. As an enema it will also produce its effect in doses of thirty grains.

Beaumont Small.

HYPNONE (Acetophenone). Chemically this compound is methyl-phenyl-ketone, $C_6H_5CO\,CH_3$. It has long been known, but its therapeutic properties were studied and demonstrated by Dr. Dujardin-Beaumetz and Dr. Bardet, in 1885, at which time it was given the shorter name of hypnone. They considered it a very valuable hypnotic, even superior to chloral and paraldehyde, particularly in the insomnia due to alcoholism. Dose, two to four drops. It is a colorless liquid, sp. gr. 1.032. At 57.2° F. it solidifies into a mass which persists to a temperature of 60° F. It is volatile and its odor is very penetrating, recalling that of the oil of bitter almonds. It is not soluble in water nor in glycerine, but is soluble in alcohol, ether, and oil of sweet almonds. It has a sharp, almost caustic taste, and requires to be given well diluted or with the oil of sweet almonds, in capsules.

Further employment of this drug has not supported the views of its discoverers. Its action has proved uncertain, and it is not of any service when the sleeplessness is due to pain. It is only indicated in primary and nervous insomnia, when other soporifics have failed. A further objection to its use is its disturbing effects on the digestive organs and its ill effects on the blood. The following conclusions are formulated by Kamensky: (1) Hypnone enfeebles sensibility and diminishes the reflexes; (2) moderate or large doses produce a slight sleep resembling natural sleep when the drug is introduced directly into the blood; (3) it increases the heart-beat, probably by stimulating the accelerator centre of the heart; (4) in moderate quantities it increases respiration, but large doses paralyze it; (5) it depresses arterial pressure by paralysis of the vaso-motor centre and enfeeblement of the heart's energy; (6) moderate and large doses diminish the excitability of the cerebrum, while all quantities increase the excitability of the spinal cord; (7) it reduces the oxyhæmoglobin of the blood; (8) it diminishes temperature by increasing heat dissipation.

Beaumont Small.

HYPNOTICS. Numerous chemical products have lately been found to produce sleep, and have been tried as hypnotics in cases of insomnia. Most of them proved uncertain and disagreeable in action; a few, however, especially chloralamide, sulphonal, and amylene hydrate, have been found to act with much certainty, and without

* It may also be formed by shaking together concentrated solutions in the above proportions, the crystals being deposited. If the chloral be in excess, the crystals form in prismatic needles.

markedly affecting the functions of circulation and respiration. In some respects they seem to be superior to the old, well-known hypnotics, and hence will probably come into general use, and occupy a prominent place among the standard remedies for insomnia.

CHLORALAMIDE, OR CHLORAL-FORMAMIDE.—Chloralamide was introduced in 1889, by Professor Von Mering, as a substitute for chloral in cases of insomnia in which the influence of chloral on the organs of circulation should be avoided. He supposed that the formamide, contained in chloralamide, would effectually prevent the depressing action of chloral.

Chloralamide is prepared by mixing molecular weights of chloral and formamide, that is, 147 parts of anhydrous chloral and 45 parts of formamide. The liquids combine and form a crystalline solid, as represented by the following equation :

$$\underset{\text{chloral}}{C\,Cl_3\,COH} + \underset{\text{formamide}}{HCONH_2} = \underset{\text{chloral-formamide}}{C\,Cl_3\,CH\,(OH)\,HCONH}$$

Chloralamide is in the form of white, lustrous crystals, having a bitter taste, but no odor. It is slowly soluble in 20 parts of water, and in 1½ part of alcohol. It decomposes in hot water having a higher temperature than 60° C. ; so also in alkaline solutions, but not in dilute acids.

Physiological Action.—Chloralamide does not irritate the mucous membrane of the stomach, and is not affected by the gastric juice. After absorption it is slowly decomposed by the alkaline blood into chloral hydrate and formate of ammonium. The latter is produced as follows : $HCONH_2 + H_2O = NH_4CHO_2$. Consequently, the action of chloralamide is that of chloral hydrate, modified by the rate of its decomposition in the blood, and possibly by the presence of the formate of ammonium.

The experiments made upon animals have yielded somewhat discordant results, not as to the influence of chloralamide on the brain, but as to its action on the organs of circulation and respiration. Von Mering,[1] Kny, and others noticed no fall of blood-pressure in rabbits under the influence of hypnotic doses of chloralamide ; Laanggaard,[2] on the contrary, observed decided lowering of blood-pressure, although this effect supervened more slowly than after chloral hydrate.

Upon man chloralamide acts like chloral, except that it produces sleep less rapidly and less certainly. As a rule, after doses of 2.0 to 3.0 (thirty to forty-five grains) sleep ensues in half an hour, and continues from five to eight hours. During the sleep, the functions of circulation and respiration are performed as vigorously as in normal sleep. After awakening the patient presents no disagreeable after-effects.

Numerous deviations, however, from this ordinary action have been observed, depending chiefly upon the causes of the insomnia. Thus, in cases of intense excitement of the brain, of severe pain, of harassing cough, and of high fever, doses of 2.0 to 3.0 have failed to produce sleep, and sometimes even 4.0 (sixty grains) have been ineffectual. Often, even when the causes of insomnia were not intense, sleep did not supervene before an hour, sometimes two hours, and in rare instances even three hours. In some cases of heart disease,[3] especially in valvular disease with imperfect compensation, a very decided depression of the circulation has been observed. So, too, in typhoid fever a very unfavorable effect upon the pulse was noticed after 2.0 (thirty grains) given in divided doses.

Generally, after-effects do not occur, or they are very trivial, consisting of headache, slight giddiness, a feeling of fatigue, and skin eruptions.

From the above it is evident that chloralamide closely resembles chloral in action, but that it induces sleep more slowly and less certainly, and that it is less apt to depress the circulation. The differences seem to be due to slow and gradual liberation of chloral in the blood, although it is not improbable that the presence of the formate of ammonium may somewhat modify the action of the chloral on the organs of circulation. The variations in the rapidity of action doubtless result from differences in the rate of decomposition in the blood of different persons.

Therapeutic Uses.—Chloralamide is a suitable hypnotic in insomnia not caused by intense excitement of the brain, very severe pain, or extreme dyspnœa. When severe pain causes insomnia, chloralamide alone is not very efficient, but it acts well if given together with a moderate quantity of morphine. In the insomnia associated with mild nervous excitement, with neurasthenia, and with somatic diseases in general, moderate doses, from twenty to thirty grains, are usually effectual. Such moderate doses having frequently failed in cases of intense mental excitement and severe pain, larger doses, as much as one drachm, have been recommended ; but it should be recollected that such large doses may cause dangerous depression. Even moderate doses should not be given in cases of heart disease, if the heart's action be very feeble, or if symptoms of inadequate compensation be present. In no case should the dose be larger than the corresponding dose of chloral hydrate. Chloralamide contains 77 per cent., and chloral hydrate 89 per cent., of anhydrous chloral.

Chloralamide may be prescribed as follows : (1) ℞. Chloralamid., ʒij.-ʒ j. ; Aq. dest., ℥ ijss. ; Acid. hydrochl. dil., gtt. v. ; Syr. rubi idæi, ℥ ss. M. S. : One half to be taken before retiring. (2) ℞. Chloralamid., ʒ j. ; Spir. frumenti, Syr. rubi idæi, āā ℥ ss. M. S. : One tablespoonful shortly before retiring.

SULPHONAL.—The properties of this hypnotic have been described in this HANDBOOK, Vol. VIII., p. 499, and need not be repeated here.

Sulphonal has been extensively used in the last four years. The results obtained by clinicians, who have had ample opportunities for observing its effects, may be summed up as follows :

1. In doses of 1.0 to 2.0 (fifteen to thirty grains) sulphonal is a very reliable hypnotic in simple nervous insomnia ; but in such doses it often fails in the insomnia caused by cough, pain, and dyspnœa. Large doses,[4] however, will generally produce satisfactory sleep ; but their action is often followed by disagreeable effects, and in heart disease by serious depression of the circulation.

2. Sulphonal continues to act in the same dose for a long time. In some cases it has been found that, after one dose had acted well, sleep would take place spontaneously on the subsequent night. It has frequently been observed that a moderate dose, 1.3 (twenty grains), would on the first night act only for a short time, but, when repeated on the following night, cause prolonged, refreshing sleep. Cases[5] have been reported in which moderate doses had been taken for months, at first nightly, and afterward several times a week, with a satisfactory result, and without any apparent injury.

3. Some observers have noticed cumulative effects ; moderate doses, repeated once in twenty-four hours for some weeks without ill effects, suddenly produced very grave phenomena, such as vomiting, prostration, and ataxia. Doses of 1.0 to 2.0 (fifteen to thirty grains) given repeatedly for several days, have in a few instances caused weakness, staggering, grinding of the teeth, difficult articulation, and severe giddiness. In one case 20.0 (three hundred grains) taken within a week, caused severe vertigo, great restlessness, confusion of mind, loss of memory, and clonic spasms.[6]

4. The prolonged use has in some instances been followed by serious disease of the kidneys, and changes of the blood.[7] The urine had a dark-red color, and contained much coloring matter, albumin, and tube-casts. Some of the patients died from heart-failure. The doses were moderate, usually from 1.0 to 2.0 daily.

AMYLENE HYDRATE,—$C_5H_{12}O$.—Dimethyl-ethyl-carbinol $(CH_3)_2C_2H_5COH$. Amylene hydrate is a limpid, volatile, neutral liquid, having a peculiar, spicy odor, and a pungent taste. It is soluble in eight parts of water, and readily mixes with alcohol, ether, chloroform, glycerine, and fixed oils. It boils at 99° to 103° C. Its sp. gr. is 0.815 to 0.820.

Physiological Action.—Professor Von Mering[8] investigated the action of amylene hydrate in experiments upon

animals. In rabbits, doses of two to three grammes in ten to twenty minutes produced sound sleep, which continued from six to eighteen hours. In dogs, proportionate doses were followed in half an hour by sleep, which lasted from ten to eighteen hours. During the sleep no notable change took place either in respiration or in circulation. No lowering of blood-pressure was found when the narcosis was so deep that all the reflexes had disappeared. Moderate doses acted chiefly upon the cerebrum; but large and toxic doses affected also the spinal cord and the medulla oblongata; first the reflexes ceased, then the breathing stopped, and finally the heart stood still.

In man moderate doses cause prolonged refreshing sleep, without affecting the heart, the respiratory apparatus, or the alimentary canal. Poisonous doses produce symptoms resembling those of alcoholic intoxication—deep, long-continued sleep, with complete suspension of motility, sensibility, and reflex action; dilatation of the pupils; slow, irregular, superficial breathing; slow, small pulse, and lowered temperature. No cases of death from amylene hydrate have been reported.

Therapeutic Uses.—Having observed the genial action of amylene hydrate upon animals, Von Mering tried it clinically in cases of insomnia. To 60 patients affected with sleeplessness he gave 350 doses. After doses of 3.0 to 5.0 (forty-five to seventy-five minims), sleep ensued within half an hour, and continued from six to twelve hours. Only four times was the hypnotic action unsatisfactory. No disagreeable incidental effects occurred, and only one patient complained on the following morning of slight headache. When the sleeplessness was due to pain, amylene hydrate did not act well; but the simultaneous administration of a small quantity of morphine rendered the action satisfactory. No deviation from the normal condition took place in the functions of respiration and circulation, and in several cases of heart disease with insomnia, quiet sleep resulted without any disagreeable effects. Von Mering supposed that 2.0 of amylene hydrate act as strongly as 1.0 of chloral hydrate, and 3.0 of paraldehyde.

A very thorough trial of amylene hydrate was made at Professor Jolly's psychiatric clinic in Strasburg.[9] To 80 patients 1,050 doses were given. Small doses, 1.6 to 2.6, were at first used in all cases; if a satisfactory result was not obtained, the dose was increased until the maximum, 4.8 to 5.0, was reached. Generally sleep ensued in from five to twenty minutes; in excited and restless patients, in twenty to thirty minutes; and in the maniacal, in one-half to one hour. During the sleep the pulse and breathing were normal in all cases. The sleep was less sound and protracted after small than after large doses, and the patients were awakened by the slightest touch, as when the pulse was counted; but this rarely occurred after large doses. No injurious incidental effects were observed. The digestive tract was never disordered, and only two or three times did nausea or vomiting occur. The appetite was not diminished, and the action of the bowels not disturbed. In very rare instances patients complained on the following morning of slight headache or throbbing in the head; but in those cases the general condition was disturbed by the primary psychical disease. Free perspiration at the beginning of the hypnotic action occurred in a few patients.

Amylene hydrate has been used to a considerable extent as a hypnotic in hospitals and insane asylums. The reports from these institutions have in general fully corroborated the observations of Von Mering, and of Jolly, of Strasburg.

The dose of amylene hydrate is 2.0 to 4.0 (thirty to sixty minims), preferably in aqueous solution, with extract of glycyrrhiza, syrup of orange, or syrup of raspberry as corrigents. The maximum dose of the Ph. G. is pro dosi 4.0, and pro die 8.0.

It may be prescribed as follows: (1) ℞. Amyleni hydrat., ʒ jss.; Aq. dest. ℥ ij.; Extr. glycyrrh., ʒ ij. M. S.. One-half to be taken at bedtime. (2) ℞. Amyleni hydrat., ʒ jss.; Aq. dest. ℥ jss.; Syrup. rubi idæi., ℥ ss. M. S.. One-half to be taken at bedtime.

Samuel Nickles.

HYSTERIONICA BAYLAHUEN, H. B. A perennial plant belonging to the order of Compositæ-Synantherеæ, and closely allied to Grindelia robusta. It is indigenous to Chili and is remarkable for the resinous exudation with which all its parts are covered. It contains a brown, odorous, acrid resin, and an essential oil. No alkaloids have yet been separated. It has a local reputation as an anti-diarrhœic remedy, and has been used with success in chronic dysentery and the diarrhœa of phthisis. The action of this plant has been studied by G. Baillé (*Bull. Gén. de Thérap.*, February, 1889). He found it very serviceable in all the diarrhœas of wasting diseases, particularly in phthisis. He recommends that an aqueous solution be prepared, 1 part to 150 of water, as the alcoholic preparation is not of any value in these troubles. Dr. H. Gilbert (*Therap. Gazette*, January, 1891) has used the fluid extract in various forms of chronic diarrhœa, and always found it serviceable. He employed the fluid extract in doses of ten minims every six hours, and continued its use for a prolonged period. No bad effect followed its use in any of his cases.

He used the tincture in lung diseases, and found that it lessened the secretion and cough, and did not irritate the stomach. The large quantity of aromatic resin which it contains has led to its use in bladder troubles and diseases of the urinary passages. It lessened the pain of micturition in cystitis and rendered the urine clearer and purer.

Beaumont Small.

ICHTHYOL. This compound is obtained by the distillation of a bituminous mineral deposit of Tyrol, which contains an abundance of the fossil remains of fish and other marine animals. During the dry distillation there passes over, between 100° C. and 225° C., a crude volatile oil. This is treated at 100° C. with an excess of concentrated sulphuric acid, which forms ichthyo-sulphonic acid, and this is precipitated by the addition of concentrated brine. The product contains a certain proportion of the unchanged oil, which cannot be removed without producing decomposition of the whole compound.

Ichthyo-sulphonic acid forms salts with ammonium, sodium, lithium, zinc, and mercury, but the ammonium salt is the one preferred and generally understood by the title of ichthyol. Ammonium ichthyol sulphonate, $C_{28}H_{30}S_3O_6(NH_4)_2$, is a clear, thick, brownish liquid with a smoky bituminous odor and taste. It is soluble in water, in a mixture of alcohol and ether, in glycerine, oils, and fats. Experiments on animals show that it does not possess any toxic properties, and but one instance is recorded where very distressing symptoms followed the application of one part ichthyol to two parts of glycerine, to the enretted surface of the uterus. The patient complained of the taste of the drug, tachycardia and general depression came on, and the patient remained prostrated for twelve hours. The symptoms were supposed to be due to absorption of the ichthyo-sulphonic acid through the abraded surface of the uterus.

The therapeutic value of ichthyol depends upon three

factors: its reducing property, its antiseptic action, and a contractile effect which it exerts on the vascular system. It was introduced by Dr. Unna, of Hamburg, in 1883, as a remedy for the treatment of various forms of skin disease. Its use has since been greatly extended, and it is very generally used, both externally and internally, in a great variety of diseases. Unna described it as the remedy *par excellence* against acne, the pustular as well as the papular form. He advises fifteen drops internally twice a day, and a ten per cent. lotion to be painted on at night; each day the part was to be bathed with hot water and ichthyol soap. In rosacea it was equally beneficial, but in eczema, or in either of the above skin affections approaching eczema, it had to be used cautiously and more mild applications employed. He also recommended it in lichen, urticaria, intertrigo, erythema, furunculus, burns, and innumerable other forms of skin disease. In eczemas he found benefit from the internal use of ichthyol and mild soothing applications. Subsequent experience has confirmed the value of this remedy in nearly all forms of skin diseases, including eczema and all forms of eczematous inflammations. Externally it is employed as a lotion of the strength of ten or twelve per cent., or as an ointment with lanoline or other base. Dr. Unna has recently advised the preparation of varnishes, which he considers the most suitable way of applying the remedy: Ichthyol, 40 parts; starch, 40 parts; solution of albumin, 1 to 1½ part; water, to 100 parts. The starch is first moistened with the water, the ichthyol is then added, and lastly the albumin. For surgical purposes he uses: Ichthyol, 25 parts; carbolic acid, 2.5 parts; starch, 50 parts; water, 22.5 parts; the ichthyol and carbolic are dissolved in the water, warmed, and when cool the starch is added. These varnishes may be applied and remain on the parts until the next application, and are easily removed by water.

A more important addition to the therapeutic value of ichthyol has been its employment in erysipelas. Klein found that in dilute solutions it arrested the development of the bacilli of erysipelas, and when used in the treatment it shortened the attack by one-half. The parts should be carefully washed and an ointment of equal parts of vaseline and ichthyol applied; where the surface affected was extensive a weaker application was used—ichthyol, lanoline, and water in equal parts. The applications should be thoroughly rubbed in two or three times a day, and continued for five or six days, when the redness and inflammation will be found thoroughly removed. In using the application the clothes and bedding should be protected.

This drug has not been employed to any extent in general surgery, although it has been recommended as a dressing for wounds, abscesses, and ulcers, in which it undoubtedly possesses a beneficial action. Unna advises the use of the pure, undiluted ichthyol for such purposes. In gynæcological disorders it is much used, and reports of its success are numerous. In chronic forms of parametritis and perimetritis, with exudations and adhesions, inflammatory conditions of the ovaries and tubes, cervical erosions, vaginal catarrh, it causes a lessening of the congested condition, and promotes absorption of the inflammatory products. In no instance has it produced any unfavorable symptoms, and as a wash and tampon it may be used without danger. It may be used with glycerine, one to twenty, as a tampon, with lanoline in equal parts, or a ten per cent. solution in water may be used as a wash. It is also given internally, which assists the action of the typical application in promoting absorption.

On account of its success in gynæcological practice, it has been employed in inflamed conditions of the prostate, a ten per cent. solution being injected into the anus three or four times a day. It appeared to have a very favorable action on the inflamed gland, and in forty cases in which it was used, no abscess occurred in any case.

It was advised as a remedy in rheumatism, particularly in the form due to gonorrhœal infection, but experience has not proved it a success. An ointment is rubbed in the affected joints, and five to twenty minims are taken internally each day. At the meeting of the Fourth International Congress, Dr. Unna read a paper pointing out the value of ichthyol in the treatment of leprosy. He presented the following conclusions: (1) Lepra tuberosa, even of universal extension and more than one year's standing, can be cured; (2) the cure can be effected in a comparatively short time by the energetic internal and external employment of the reducing remedies; (3) among them may be specially recommended ichthyol, chrysarobin, pyrogallol, and resorcin. Of these ichthyol is the only one that can be administered internally, without danger, for any length of time, and consequently is a remedy of great importance. The application advised is an ointment of ten parts ichthyol, seven parts lard, and oil, three parts. Internally, fifteen to twenty-four minims may be taken daily.

In addition to the diseases enumerated, it may be administered internally in all conditions in which there is hyperæmia and capillary dilatation. It in no way disagrees with the patient, although at first it may give rise to disagreeable eructations of gas; this, however, does not persist. It does not cause any irritation of the mucous membrane, but has been found beneficial in all forms of chronic gastric and intestinal troubles. The dose for a child of two years of age is about two minims daily; for adults, from five to twenty minims daily. It is usually administered in pills or in capsules.

Beaumont Small.

IDIOPATHIC ANÆMIA.—Much study has been given to idiopathic anæmia since the publication of the REFERENCE HANDBOOK. Its clinical characteristics, particularly those of the blood, have been more sharply defined, but there is still a lack of entire agreement as to its pathogeny. The most important papers which have appeared in recent years are those of Hunter, Russell, and Mackenzie.

The blood changes in idiopathic anæmia are, with few exceptions, such as may occur in any grave chronic anæmia, but in the former they are more varied and reach a more intense degree. A very important characteristic is the amount of hæmoglobin present; the whole amount is diminished, but, as compared with the greatly diminished number of red blood-corpuscles present, the hæmoglobin is relatively increased. Again, there is great variation in the size of the red blood-corpuscles, the average size probably being larger than normal. The number of nucleated red blood-corpuscles varies, and as they are found in other anæmic conditions their presence alone is not significant; but the occurrence of a considerable number of nucleated cells of large size (gigantoblasts) is regarded by Ehrlich and his followers as almost diagnostic of idiopathic anæmia.

The leucocytes of idiopathic anæmia are diminished in number, the proportion of small mononuclear cells (lymphocytes) being increased, and that of multinuclear cells diminished.

Minute examination of the blood requires that cover-glass preparations should be made, and the blood stained. For this method we are indebted largely to Ehrlich. The cover-glasses should be perfectly clean, and to avoid soiling or moisture it is advisable to use forceps. A satisfactory solution for staining is the following, suggested by Dr. W. S. Thayer:[1]

Sat. aqueous sol. of orange G.....	2
Sat. aqueous sol. of methyl green....	6.25

To be added, drop by drop, while shaking the solution:

Water.....	15
Alcohol.....	10
Glycerine.....	5

The cover-glass preparations of the blood are first fixed by immersion in equal parts of alcohol and ether, or, what is better, by heating them at a temperature of 212° F. or a little higher; but they should not be kept at that temperature more than an hour. They are then stained in the solution mentioned for from two to five

minutes, washed in water, dried, and mounted in oil or balsam. "The red cells are stained orange or buff, the nuclei of the colorless corpuscles green, the neutrophilic granules violet or lilac, the eosinophilic granules a deep red. The nuclei of the nucleated red blood-cells are stained an intensely deep green, almost black."

As regards the pathology of idiopathic anæmia, Hunter's investigations seem to show conclusively that hæmolysis is at least the largest factor in idiopathic anæmia. He, by the way, looks upon pernicious anæmia as a special disease, and as a distinct variety of idiopathic anæmia.

Hunter found the most constant anatomical change to be a large excess of iron in the liver. He concludes that: "In pernicious anæmia the seat of disintegration is chiefly the portal circulation, more especially that portion of it contained within the spleen and the liver, and the destruction is effected by the action of certain poisonous agents, probably of a cadaveric nature, absorbed from the intestinal tract."

Griffith and Burr[2] reach essentially the same results as Hunter.

W. Russell believes that the blood is defective before it reaches the liver, and that this explains the increased liver hæmolysis.

As regards treatment, it is important to keep the stomach and bowels in a healthy condition. Washing out the stomach is a rational procedure, and is reported to have cured one case (Meyer).

The bowel should also be kept free from putrefactive changes by laxatives and antiseptic agents. Dr. G. A. Gibson,[3] adopting Hunter's suggestion, employed β-naphthol in two-grain doses three times a day in a case of pernicious anæmia. Apparent cure resulted. The β-naphthol is best given with salicylate of bismuth, to prevent intestinal disturbance. Hunter prefers farinaceous and fatty foods to meats. Of internal remedies, arsenic is unquestionably the best. It should be given in as large doses as can be borne; some patients have been able to take as high as twenty to thirty minims of Fowler's solution at a dose. Inhalations of oxygen have also proved helpful.

ILFRACOMBE. A popular sea-side resort and climatic station in North Devonshire, England. Ilfracombe is situated near the mouth of the British Channel, and is surrounded by peculiar picturesque heights called "tors." The climate is bracing, but not mild and equable. It is less rainy, however, than at Torquay. The sanitation of the place is good. The rate of mortality is only about seventeen per thousand per annum. According to Black ("Watering Places of England"), Ilfracombe is "a good-sized seaport town, formed principally by one main street, about a mile long, running parallel with the sea-shore, and a harbor (formed by an inlet of the Bristol Channel), which is almost encircled by picturesque verdurous heights or tors. It is remarkable for a peculiar form of coast, rarely to be met with elsewhere in England. Beginning with the harbor of Ilfracombe itself, the land and sea together combine in making constant alternations of high, craggy, furze-crowned tors, in some cases almost overhanging the sea below, which precipitately break and give place to little bays or inlets, separating and varying what would otherwise be a continuous line of cliffs—thus allowing glimpses of the inland foliage beyond."

The bathing facilities are good, but there are no sands fit to stroll on. One of the features of the beach is a peculiar vaulted passage leading to two coves, one for ladies, the other for gentleman bathers. Interesting excursions abound in this section of Devon. The height of the season is from July to October. Ilfracombe is about six and a half hours by rail from London.

Edmund C. Wendt.

IMMUNITY, ARTIFICIAL. As will be seen from the article "Artificial Immunity" (p. 51), in Ehrlich's experiments upon the transmission of immunity, this observer found that immunity in the father has no influence upon the offspring: the offspring of a highly immune father are just as susceptible as those of a highly susceptible father. Immunity can only be transmitted by the mother, and this takes place in two ways: by intra-uterine transfer of immunity from the mother to the fœtus, and by extra-uterine transfer with the mother's milk. Moreover, the milk of an immunized animal will not only give immunity to the offspring of the animal herself, but can also be used by feeding or by subcutaneous injection to render other animals immune. Now, since the article above referred to was cast, and consequently after it was too late to make any additions, there have appeared two publications: one on the transmission of immunity by the male, and the other upon the variability in the immunizing power of the milk of an immunized animal. The first of these articles[1] goes to prove that in hydrophobia a male dog does transmit immunity to his offspring; this is in striking contrast to Ehrlich's results. It was shown that in rabies highly protected male dogs in two out of three cases transmitted a high degree of immunity to a part of a litter (two out of five in one case, and two out of four in the other). In the third case, where there were four puppies, there was no evidence of transmission at all. In those cases where immunity was transmitted the puppies resisted the inoculation of the spinal cord from a case of "street-rabies" under the dura mater. Animals died of hydrophobia in the check experiments. The three remaining puppies of the first experiment, and all four of the third, died of hydrophobia on subdural application of spinal cord from a case of street hydrophobia. The two puppies which died in the second experiment took the disease from inoculations under the dura with the "virus fixe," a more powerful virus than that of the street. The fathers of each of the litters of puppies were different, but all three were highly rabies-proof. The mothers were all normal, *i.e.*, not rabies-proof.

The small number of these observations and the conflicting results necessitate substantiation before the transmission of immunity from rabies by the male can be accepted as proven.

The other publication[2] referred to above gives the results of further tests of the power of the milk from the goat, which was given immunity from tetanus during and after gestation (mentioned under "Artificial Immunity" on p. 51). It shows that the power of the milk is subject to considerable fluctuation, depending upon the length of time that may have elapsed between the inoculation of the goat and the making of the tests. Some time after the goat had been inoculated it was found that its milk had 4,000 degrees immunizing power. The goat was then inoculated with 75 c.c. of a virulent tetanus culture, and showed no symptoms; but twenty-four hours after this inoculation the milk showed that its immunizing power had fallen to 1,000, and further tests showed that it remained at 1,000 for a day and then gradually rose, attaining a value of over 8,000 in eighteen days. It then gradually fell to below 4,000 in seventeen days, where it remained stationary.

The explanation given of this behavior is that at first some of the antitoxin contained in the milk had to be used to counteract the poison contained in the virulent culture injected into the animal, and this was followed by an over-production of antitoxin. In other words, it is an analogous process to the over-production of leucocytes following extensive destruction of these. Other processes of a similar nature are often met with in biological investigation.

In testing the value of the milk or blood-serum of a goat made immune from tetanus, it is seen from the above that the test must be made at least four or five weeks after the last inoculation, otherwise the result will not be uniform.

The antitoxin contained in the milk was obtained in a concentrated state by precipitation with ammonium

sulphate, dialysing in running water, and drying in vacuo at 35° C. There resulted a yellowish-white powder possessing powerful antitoxic properties.

INFLUENZA. *Influenza* is an acute, self-limited, infectious fever, occurring in widely distributed epidemics, and characterized by catarrhal inflammation of the respiratory and gastro-intestinal mucosa, by profound nervous disturbances, and by extreme debility.

Synonyms.—Febris Catarrhalis; Epidemic Catarrhal Fever; La Grippe; Grip; Tac; Horion; La Dando; Ziep; Epidemischer Husten; Epidemischer Schnupfen; Schafhusten; Blitz Catarrh; Mödefieber; Mal Russe; Snufsjuka (Swedish); Qual-Tong (Chinese).

Many other synonyms, grave and humorous, might be listed which have been suggested by the peculiarities of various epidemics, the national characteristics of the people affected, or some fancied resemblance of the symptoms, but *influenza*, *la grippe*, or the Anglicised *grip*, have practically superseded all other names, in medical as well as lay circles.

Influenza is of Italian origin, and was probably first employed by the Italian savants to indicate the supposed occult influence of the stars over the course of the disease. Wolff states that it was first used by an Italian author, Gagliardi: "Parere sopra l'Influenza catarrale, che presentamente regna in Roma e stato ecclesiastico, Roma, 1733."

Other authorities, however, trace its origin to the English writers Pringle and Huxham, the latter of whom, in describing the epidemic of 1742–43, writes: "Quæ per totam Europam hoc vere sub nomine influenza grassata est."

The derivation of *la grippe* is likewise in doubt. Most authors refer its origin, and probably correctly, to the French, *agripper*—to seize, but others derive it from the Polish, *chrypka*, or *grypka*—hoarse. It came into general use in France during the epidemic of 1732 (Marigné: Description et traitement d'une affection catarrhale epidémique observée en 1732, vulgairement appellée la Grippe, 1776).

Historical Sketch.—Since the appearance of the fourth volume (1887) of this Reference Handbook, containing the brief article on *Influenza*, a series of epidemics has swept over the world, which, for rapidity of movement, extent of distribution, and numbers affected, rival any previous visitations of the disease. This series, which began in the fall of 1889, and which can hardly yet be spoken of as an event of the past, was the first general epidemic of la grippe since 1847–48, and really introduced the present generation of practitioners to a disease known to them only in history, and thus becomes one of the notable medical events of the latter half of the century.

Recurring at a time when the study of the infectious diseases was being pushed so zealously along bacteriological lines, and engaging in its study the ablest clinicians of every nation, it was confidently predicted that the mysterious problem of its nature and etiology would be speedily solved. While this prediction has not been fulfilled, our knowledge of epidemic influenza has been materially increased and necessitates a restatement here.

In this necessarily brief historical sketch we shall not attempt a complete chronological account of the epidemics of all ages but shall only allude to those which, from special incidents, mark an era in the progress of our knowledge, and endeavor to trace somewhat in detail the course of the recent epidemics of 1889–92.

Medical historians have interpreted the vague utterances of Hippocrates and Livy, referring to a disease which assumed epidemic proportions in 412 B.C., as the first written allusion to influenza.

Mention is made of an epidemic which prevailed extensively in the latter part of the sixth century, in which the prominent symptoms were headache, debility, cough, and an irresistible desire to yawn. Sneezing was usually the first symptom of the prevailing distemper, and the custom of calling down "God's blessing" upon one who was heard to sneeze is said to have originated at this time.

It is very probable, as maintained by many authors, that not a few of the general epidemics described in the earlier medical chronicles under various names (catarrhal fever, Italian fever, etc.), were epidemics of true influenza.

Parkes traces the disease back to the ninth century. In 827 and 876 epidemics in which cough was the most prominent symptom, and which also extended to domestic animals and birds, originated in Italy and spread rapidly over all Europe. The epidemic of 876 is said to have sadly discomfited the victorious army of Charlemagne on its return march from Italy.

But one epidemic, and that limited to Germany and France, is known to have occurred in the tenth century, after which the world apparently enjoyed immunity for about two hundred years.

Whatever may have been the nature of these early epidemics, our positive knowledge of influenza, according to Wilson, dates from the great visitation of 1510, which covered the whole of Europe and the British Islands, and was so general that "not a single family and scarce a person escaped it."

The epidemic of 1557, which appeared suddenly in Eastern Asia and spread rapidly to the West, was the first influenza epidemic which is known to have crossed the Atlantic to America. This pandemic was very severe in certain localities and was attended with a high mortality. Five thousand are said to have died in Delft alone within a short period.

During the past four hundred years there have been about seventy epidemics of grippe, one-half of which, from their widespread prevalence, deserve to be called pandemics.

The present century has experienced thirteen visitations; the last important one previous to 1889 was that of 1847, in which were stricken more than one-quarter of the population of London and Geneva, and fully one-half that of Paris.

The course of the later epidemics has been quite uniformly from east to west. It is, of course, only the general trend of the epidemic that can be followed, since every locality invaded becomes at once a new centre from which arms of infection reach out in every direction. With few exceptions, the later pandemics of influenza originated in Eastern Asia, where the disease may almost be said to be endemic. From this nidus they travelled westward across Russia, thence over Continental Europe and the British Isles, over the ocean to America, Australia, East Indies, until, like Puck's girdle, they circled the globe.

The epidemic of 1889–90 followed closely the beaten path. The first cases, of which we have knowledge, occurred in Bokhara, Central Asia, in May, 1889. The disease became quite prevalent in July, and following the lines of the new railways slowly invaded other portions of the Russian Empire.

The epidemic can be easily traced through Western Siberia and the post-towns and stations in Russia in its march toward St. Petersburg, which was reached by the end of October, and two weeks later it had assumed such startling proportions in that city as to attract the attention of the civilized world.

From St. Petersburg the epidemic spread with unprecedented rapidity, and the cities of Western Russia, Central and Northern Germany, Austria, France, and the British Islands became, in turn, the scene of its ravages, until by the end of December it had compassed the whole of Europe. Scattering cases announced the appearance of the disease in New York about the middle of December, and a week later it had assumed epidemic proportions. From the seaboard it extended in every direction, and during January, 1890, was generally diffused over the United States, British North America, the Sandwich Islands, and Central America (Guatemala.)

From its starting-point in Central Asia the epidemic also extended in a southeasterly direction. Malta, Cyprus, and Egypt were successively visited in January and February. It was reported from India in February, became epidemic in March, and prevailed extensively in Upper and Lower Birmah during April and May. It reached Arabia in April, many of the pilgrims arriving from India and the Straits having sickened on the voyage.

In the Southern hemisphere the course was from the south northward. Capetown was the seat of its first appearance in Africa, it having been carried thither by steamers; thence it extended northward, reaching Mauritius in August, the Shire Highlands in September, and Abyssinia in November, 1890.

South America was reached in February. Buenos Ayres was infected presumably by steamer from Bordeaux; thence it travelled up both coasts and prevailed in Brazil, Chili, and other States during April and May. It was notably severe in the province of Pernambuco. It was prevalent in Australia and New Zealand from March to July.

In Iceland it occurred in July, and in some remote places of China and Kashmir during September and December.

Dr. Parsons, in his exhaustive report to the British Medical Association, July, 1891, to which we are largely indebted for the facts above related, writes: "Thus assuming the epidemic to have started from Russia in October, it took about six weeks or two months to spread over Europe and reach North America, rather more than two months to reach the Cape, three months to reach South America, four months to reach India, five months to reach New Zealand and Australia, nine months to reach Iceland, ten months to reach Mauritius, and nearly a year to make some remote places in Africa and Asia."

During the summer and fall of 1890 influenza was "smouldering on," as shown by the numerous local outbreaks, usually of short duration, in different parts of the world.

The second general epidemic—1891—began in January, and was but little less extensive, and probably more fatal, than the one just sketched. It, too, was pandemic, but in the journey around the world the course of its predecessor was reversed, and the general trend was from west to east.

The origin of the epidemic is traced to New Orleans, where influenza prevailed extensively and fatally in January, and from which it radiated in every direction. During February, March, and April it spread over the Northern States and was notably severe in Pittsburg and Chicago (March) and the sea-board (April). It was reported from England in April, from Germany in August, from Scandinavia and Denmark in July, from Russia (St. Petersburg) in September, from France in October, from Italy in December, and thus passed from country to country until almost the whole civilized world had been revisited. This epidemic also ran its course in about one year.

Nature and Etiology.—It has been customary to consider influenza as an epidemic catarrhal fever, but recent *dénouements* have materially strengthened the belief, long entertained by some, that it is really an infectious nervous fever.

Many of the symptoms are most readily explicable upon a neural basis, while its probable bacterial origin, together with the knowledge of the toxæmias that usually attend upon bacterial infection, gives support to such an explanation. Much testimony has accumulated during the recent epidemics to show that the nervous symptoms are primary and are followed by secondary involvement of the respiratory and digestive organs. In a given case the pulmonary, gastro-intestinal, or cerebro-spinal symptoms predominate as the nervous apparatus of one or the other system bears the brunt of the disease.

Nervous symptoms are uniformly present and usually pronounced, even in the mildest forms of grippe, while, on the other hand, in many of the worst cases, catarrh of the mucous membranes and inflammation of the respiratory tract are totally absent.

Again, when catarrh and pneumonia are present, they frequently assume "such a peculiar character as to lead to the suspicion that they might arise from irritation of, or loss of power in, the various nervous mechanisms supplying the affected parts, and would therefore have to be looked upon more as vaso-motor and trophic neuroses than as ordinary catarrh and inflammation."

The histories of the various epidemics prove clearly that the disease is not dependent upon climate, soil, season, meteorological, or electrical conditions. It affects all classes of people, irrespective of nationality, sex, social position, or environment, although infants and young children seem to possess partial immunity. While no season of the year is exempt, late autumn and early winter are the periods of its greatest frequency.

The phenomena of influenza are only comprehensible upon the theory of a specific infecting virus or germ as the exciting cause. Its epidemic occurrence, transmission along lines of travel, rapid diffusion, sweeping over whole continents in a few weeks, and affecting nearly the entire population in a certain district in a few hours after its appearance, indicate some powerful morbific agent in the atmosphere which acts specifically upon the animal economy.

Some authors still cling to the theory that the morbific agent is a miasmatic material, but the most generally accepted doctrine, and the one most in accord with our knowledge of the etiology of other infectious diseases, is that which makes it dependent upon the presence of a micro-organism.

Notwithstanding the diligent search of bacteriologists during the past three years, working under the improved modern technique, but little is positively known about the morphology of the pathogenic bacillus and absolutely nothing about the chemical constitution of its special toxine. These investigations have uniformly disclosed the presence of the pyogenic bacteria and the diplococcus pneumoniæ, but it is not claimed that they bear a causal relation to the disease.

From time to time the discovery of the grippe microbe has been announced. But, like Weichelbaum's lancet-shaped diplococcus, Klebs's flagellatum, Jolly's cossack-shaped coccus, Kirschner's punctiform microbe, and Babes's radiated bacterium, each, in turn, has failed in the crucial test and has been relegated to obscurity, along with Saulsbury's infusoria and Seifert's micrococci.

It is again confidently announced that the true influenza bacillus has been, at last, successfully and independently demonstrated by Staff-Surgeon Richard Pfeiffer and Dr. Canon, of the Moabit Hospital, Berlin. According to these observers, it is a tiny rodlet of about the thickness and half the length of the bacillus of mouse-septicæmia. It is the smallest bacillus yet isolated, and is only recognizable during the first twenty-four hours by means of a lens, so that macroscopically a test-tube containing them can scarcely be distinguished from a sterile one. The bacilli are, however, readily differentiated by the peculiarity of their growth, as the colonies always remain separate and do not, like the colonies of all other species of bacteria, join together and form a continuous row. They have been found in large numbers in the blood, sputum, bronchial, and pleural exudations of influenza patients.

Dr. Kitasato has successfully cultivated the bacillus in glycerine-agar to the sixteenth generation. Inoculation experiments have been negative in some species of animals (guinea-pigs, pigeons, mice), but in others, notably monkeys and rabbits, have caused a disease simulating grippe in its main features. Letzereich, of Wiesbaden, has quite recently published an account of control experiments in fifty cases of infectious diseases, viz., measles, scarlet-fever, diphtheria, pneumonia, and catarrhal affections of the respiratory passages, in which in neither blood nor sputum was the Pfeiffer-Canon bacillus found.

Corroborative testimony comes from others high in authority like Professors Babes and Cornil, and even Koch himself is said to have given a partial endorsement to the claims made. It is premature, in the face of the dis-

appointments of the past, to give a positive opinion, but at present it looks as if the Pfeiffer-Canon-Kitasato bacillus were indeed the true pathogenetic microbe of epidemic influenza. Should this be confirmed it will add another to the brilliant triumphs of the present decade.

It is highly probable that the action of the morbific principle of grippe is not limited to man. Epizoötics, very similar in many respects to the epidemics in the human race, have often prevailed among domesticated and wild animals, especially horses, dogs, and cats.

The attention of the profession was first called to this fact by Huxham in connection with the epidemics of 1732–33. These epizoötics occur independently, but more often happen either simultaneously with, or immediately precede or follow, epidemics of influenza. Bartholow favors the view that the epidemic disease in animals is the parent of that in man, but is so modified by transition that each succeeding epidemic is milder and less aggressive.

The contagiousness of influenza has long been a mooted question. The doctrine that contagion is one method of its propagation has been strengthened by numerous observations made during the recent epidemics and is now fully accepted by most clinicians.

The frequency with which epidemics, both in their general and local distributions, follow the regular lines of travel, the immunity of isolated households and communities, and the frequency with which local outbreaks have been traced to their sources leave, indeed, little room for scepticism. The marvellous rapidity with which influenza sometimes spreads in a community once infected is readily accounted for by its remarkably short period of incubation. It is claimed by many that personal contact with infected individuals or materials is the only method of its propagation. The supporters of this doctrine contend that the dissemination of disease-germs through the air must have its limitations. That they can be carried thousands of miles in air-currents without dispersion or destruction, or the assumption, on the other hand, of a proliferation in the air itself, does violence to our knowledge of the life history of disease-germs. There are, however, too many irregularities in the behavior of grippe epidemics, not necessary to be enumerated here, to permit us to accept personal contact as the only factor in its propagation. Hirsch has pointed out that notwithstanding the modern facilities of inter-communication and rapid transit, epidemics do not travel more rapidly now than under the old regime.

The passengers and crews of ships which have sailed from non-infected ports, and have held no communication with other ships, have been repeatedly attacked in mid-ocean.

The following striking instance is related by Sir Thomas Watson: The frigate Stag anchored at Berry Head, on the Devonshire coast, all on board well, April 3, 1833, the very day on which Watson saw his first two cases of influenza in London. The breeze was off the land, and in half an hour after dropping anchor forty men were down with influenza; six hours later the number was increased to sixty, and soon reached one hundred and sixty.

The period of incubation is very variable, both in individual cases, and in different epidemics. It may develop almost immediately after exposure, from which it has received one of its popular names, *Lightning Catarrh*, *Blitz Catarrh*, but, in other instances, there is an incubation period, lasting from a few hours to several days.

The attack does not confer immunity from subsequent ones, and a few persons even experience a second seizure during the same epidemic. An epidemic, as a rule, lasts from four to eight weeks in a given locality, although many run a shorter course and often end as suddenly as they began. The rate of progress not only varies greatly in different epidemics, but also in the same epidemic as it spreads over different districts.

There is no causative relation between influenza and other epidemic or infectious diseases. The statement that prevalent infectious and contagious diseases abate in frequency and intensity upon the appearance of grippe, is not sustained by facts. Neither is there any ground for the popular belief that cholera follows in the wake of influenza. In some instances, notably in 1831, 1847, and 1856, the two diseases have been closely associated in point of time, but the official report of the French Commission fully endorses the conclusion of Gluge and Smolensky that the association was purely accidental.

Morbid Anatomy.—The anatomical lesions found after death give meagre information as to the pathology of influenza. A fatal termination is almost invariably due to some complication, and the structural changes found *post mortem* are characteristic of the secondary disease, and not of influenza. Death rarely occurs in uncomplicated cases. The lesions peculiar to influenza are almost exclusively localized upon the respiratory mucous membrane. The mucous lining of the larynx, trachea, and bronchial tubes is hyperæmic, swollen, and covered with frothy or viscid muco-pus. The catarrh may extend to the finer bronchi, but is ordinarily limited to the trachea and larger tubes. The bronchial glands are sometimes enlarged and softened. The gastric and intestinal mucous membrane is more or less congested in a considerable portion of the cases.

The solitary and agminate glands of the intestine are not usually implicated.

Kernig, of St. Petersburg, found the spleen enlarged in all cases which came under his care.

Symptoms.—The complexus of symptoms of influenza is exceedingly varied, and this variability extends not only to different epidemics, but also to individual cases of the same epidemic. In many cases the attack closely resembles an ordinary catarrh, with little fever and slight hyperæmia of the naso-pharyngeal mucosa; again, it assumes the form of an intense infectious fever, with profound involvement of the nervous centres, while between these extremes are found cases of almost every grade of severity, and almost every combination of symptoms.

Many attempts have been made to satisfactorily classify the protean forms of the disease. The classification most generally followed by recent writers, and which is a modification of that long ago proposed by Hufeland, is into:

1. The nervous form.
2. The catarrhal or respiratory form.
3. The gastro-intestinal form.

It is estimated that in the recent epidemics about fifty-five per cent. of the cases belonged to the nervous, thirty per cent. to the catarrhal, and fifteen per cent. to the gastro-intestinal form of the disease. These estimates will undoubtedly have to be changed for different localities. According to the observation of the writer, nervous symptoms predominated in about eighty-five per cent. of the cases in the epidemic of 1889–90, while in that of 1891, the catarrhal and gastric forms were more common and severe, but still constituted a small percentage of the cases. The division is, however, purely arbitrary, and finds its chief value in emphasizing the fact that the brunt of the attack may fall upon any one of the three great systems.

Influenza usually begins abruptly, but is occasionally preceded by a feeling of indisposition or malaise of from a few hours' to several days' duration. A distinct chill, or, oftener, a mere chilliness, is at once followed by a rise in temperature and the symptoms of a naso-pharyngeal catarrh, with cough, sore throat, frontal headache, pains in, and general soreness of, the limbs, depression of spirits, and sometimes with gastro-intestinal disturbances.

The fever is remittent in type, variable in intensity, rarely exceeds 104° F. in uncomplicated cases, and subsides by lysis, rather than by crisis. As a rule, the temperature reaches its maximum at the beginning or early in the attack, and often drops below normal during convalescence.

A subnormal temperature has also been noted by many during the progress of the disease, accompanied, usually, by surface coldness, feeble circulation, and other evidences of depression. The recent epidemics were peculiar in the large number of cases in which the fever

took on a continuous type, and persisted for two or three weeks, resembling, in many of its features, a mild typhoid fever.

Anomalous cases were also recorded in which the whole course of the disease was afebrile, and, according to Eichhorst, these were particularly liable to nervous explosions.

The pulse is moderately increased in frequency and changeable in rhythm and quality. The tendency to cardiac asthenia, so pronounced in grave cases, often becomes a serious menace in those of moderate severity. An extraordinary slowing of the pulse is sometimes observed. The pulse may only register in the forties or fifties and naturally excites fears of some cerebral complication. This abnormal retardation belongs to the natural history of the disease, although it is often erroneously attributed to remedies, especially if digitalis or other cardiac sedatives have been administered.

Coincidently with the fever, and sometimes preceding it, the symptoms of an acute catarrh of the upper air-passages are manifested.

There are frequent paroxysms of sneezing, a feeling of stuffiness in the head, the eyes are suffused and watery, and coryza with an abundant secretion of mucus speedily follows. The mucous membrane of the nose, mouth, frontal sinus, pharynx, and larynx is congested. The voice becomes hoarse or reduced to a whisper. Cough is rarely absent, usually severe, and recurs in paroxysms which harass the patient day and night. At first it is harsh and brassy and attended with a scanty muco-serous expectoration, which, as the disease progresses, becomes abundant, muco-purulent, and often blood-streaked.

Sharp pains in the sides and under the sternum, dyspnœa, and suffocative paroxysms are experienced, and, as was long ago pointed out by Graves, of Dublin, often without any recognizable intra-thoracic lesion. The catarrhal process does not, as a rule, extend below the larynx or trachea, but if it should invade the lower air-passages, the deepening of the symptoms at once announces the fact, and the illness assumes a more serious aspect.

Nervous symptoms are uniformly present, but vary greatly in intensity. In some epidemics, notably in 1889–90, they predominated over all other symptoms. Severe headache, usually frontal, and pain in the eyeballs are rarely absent. The head pain comes on suddenly, is nearly continuous, dull, and throbbing, with frequently recurring paroxysms of atrocious severity. It is exaggerated by pressure or movement, and is often associated with hyperæsthesia of the scalp and neck.

With the headache there is stiffness and soreness over the entire body, as if it had been beaten, and a backache which in its intensity is suggestive of dengue or small-pox.

The patient either lies perfectly quiet, to prevent the suffering which the slightest movement causes, or tosses restlessly about in the futile effort to find a position of comfort. Sharp neuralgic pains dart along the principal nerve-trunks, but show a decided preference for the trigeminal, intercostal, lumbo-abdominal, and sciatic nerves. These neuralgias are often intermittent, but do not exhibit the periodicity of ordinary malarial neuralgias.

Persistent insomnia or unrefreshing snatches of sleep filled with painful dreams add to the patient's distress. Delirium of a mild type is usually present, and is often marked when the fever is slight. In exceptional cases it becomes so furious as to overshadow all other symptoms. Coming on late in the disease it often announces the onset of some complication.

Vertigo, especially on rising, and muscular tremor are not uncommon. Convulsions and coma are rare, but may develop with the initial fever or at any subsequent period.

The extreme muscular weakness, amounting, at times, to a serious depression of the vital powers, is a peculiar feature of influenza. The debility is wholly disproportionate to the amount of fever, or the severity of the other symptoms, and generally reaches far into convalescence.

The mental condition harmonizes with the physical depression. When thoroughly under the grippe influence, the patient shrinks from mental as he does from physical exertion, is vacillating, foreboding, and often becomes a veritable "Jacques" in his melancholy.

While restlessness and wakefulness characterize most epidemics, others are equally marked by somnolence. Thus the remarkable epidemic of 1712 is known as the *sleeping sickness*, from the almost universal presence of this symptom.

The disturbances of the digestive organs are generally mild and consist of anorexia, coated tongue, epigastric tenderness, abdominal pains and constipation. Nausea and vomiting sometimes usher in the attack and may continue throughout its course. At times, the force of the disease is expended in the intestinal tract and causes severe colicky pains, tympanites, and obstinate diarrhœa. The stools, at first bilious and fetid, soon take on a dysenteric character or become large and watery, like the discharges of cholera nostras, and are accompanied with vomiting, leg-cramps, and rapid prostration. The digestion remains impaired for some time after the subsidence of the acute symptoms, and not only retards convalescence, but favors a return of the gastro-intestinal derangements upon the slightest indiscretion of diet.

The urine is scanty, high-colored, and contains abundant urates. Albumin with casts, hyaline and epithelial, are present in a limited number of cases not necessarily of the gravest type. The integrity of the kidneys is rarely permanently impaired. Cystitis is sometimes met with, and retention of urine in elderly persons is tolerably common.

The presence of an hemorrhagic tendency has been remarked by many observers.

Epistaxis and menorrhagia are the most, and cerebral hemorrhage the least common of the accidents dependent upon this tendency.

Eruptions are occasionally seen, of which herpes, urticaria, and erythema constitute the chief examples.

The disease attains its height on the second or third day and then rapidly declines, covering a period of from four to seven days in its full evolution; but in the graver cases, or in those disturbed by complications, recovery may be indefinitely delayed.

Convalescence is often announced by the appearance of some critical discharge, such as profuse sweating, a copious secretion of bronchial mucus, a free discharge of sedimentary urine, or a profuse diarrhœa.

After complete apyrexia has ensued, there is not infrequently a temporary return of the fever and other symptoms not dependent upon the presence of a complicating disorder. This new outbreak is usually of brief duration, and should be considered as an exacerbation, rather than a relapse. It is apt to appear on the fifth or seventh day of the disease, and is oftenest seen in those who have committed some error of diet or have undergone some exposure. True, relapses are, however, not uncommon or free from danger.

Complications and Sequelæ.—While there has been, of late, a tendency to exaggerate the frequency and importance of the complications and sequelæ of influenza, the fact remains that there is scarcely another disease so liable to intercurrent disorders or to serious after-effects. The more common of these are divisible into two groups: First, those which are the direct outgrowth of the lesions in the mucous membranes and parenchymatous tissues; and, second, the sensory-motor derangements, which result from the action of the grippe toxine upon the cerebro-spinal centres. Among the rarer affections belonging to the first group may be mentioned circumscribed ulceration of the vocal cords, abscess of the larynx, œdema of the glottis and paralysis of the muscles of the throat.

Otitis media is comparatively common. The inflammation does not, as a rule, proceed to suppuration, but is rebellious to treatment and occasionally ends in mastoiditis.

Bronchitis and pneumonitis are, by far, the most frequent and fatal complications of this group. Authors

have endeavored to show that these affections, when associated with influenza, are peculiar in nature and symptomatology. According to Elliott "the grip-lung has a long and very varying condition of passive blood-stasis unaccompanied by râles. If resolution occurs within three or four days, it is accompanied by large mucous râles, and no time is given for the slow appearance of bronchial breathing or bronchophony; but during the long-continuance of the blood-stasis an exudation occurs, increasing slowly, which will give in time some bronchophony and bronchial breathing, but never so complete as in pneumonia. Resolution never occurs in these cases with the suddenness that characterizes it in acute pneumonia. The condition passes off as gradually as it is formed. The sharp, clear-cut, and sudden phases of the pneumonia attack separate it clearly from the obscure, irregular and slow phases of the grip-lung."

Da Costa, in a recent clinical lecture, describes the characteristic influenza lung as one "in which intense congestion occurs, with patches of collapse and with spots of localized consolidation here and there, if consolidation happen at all. Yet there are instances in which real croupous pneumonia takes place, involving considerable portions of the lungs. But these are comparatively rare, and true lobar pneumonia is not nearly so characteristic of the influenza lung as the other form."

Osler, with whom the writer is in full accord, admits that pneumonitis complicating influenza sometimes runs an atypical and very obscure course, but these cases are exceptional, and all the anomalies mentioned by writers as peculiar to influenza are found in any large series of cases of pneumonia.

It is highly important to bear in mind what has been previously stated, that lung complications are liable to creep on insidiously, and that in the presence of anomalous symptoms, whether referred to the respiratory tract or not, the chest, as a matter of routine, should be carefully interrogated. Pleurisy and empyema are not uncommon complications. Abscess of the lung has been noted. That influenza bears an etiological relation to phthisis pulmonalis, especially in the presence of the disposition, can no longer be doubted. It is furthermore a matter of common observation that consumptives fare badly during the prevalence of the epidemic influence.

Watson and Curtin call attention to the fact that during the recent epidemics many chronic catarrhal cases where the lungs were involved resembled closely, and were often mistaken for, phthisis. There were present night-sweats, cough, diarrhœa, fever, and emaciation, while the physical signs also agreed with those of phthisis in all but dulness on percussion, which was absent. These writers in speaking of the relationship between phthisis and influenza make the following remarkable statements: "The catarrhal condition remains and causes a breaking down of lung-tissue. These cases, while presenting the physical signs of phthisis and terminating finally in death, showed during life, on examination of sputum, no bacilli. In the fall of 1890, in the Philadelphia Hospital, the sputa of fourteen cases of phthisis examined (several times and by different methods) for bacilli showed them abundant in four, few in six, absent in four cases. In the fall of 1891, after most of the old cases of phthisis had died, twelve out of twenty-eight cases were found free from bacilli, and invariably with histories dating from an influenzal attack."

The nervous disturbances which occur during and after grippe are equally important.

Althaus reflects the opinion of neurologists in the statement: "That as a powerful etiological factor of protean forms of nerve-disease influenza stands *facile princeps* among all infectious fevers."

The organic nervous diseases most frequently observed may be enumerated in the order of their frequency, as neuritis, meningitis, myelitis, and cerebritis.

Multiple neuritis is less common than the local forms, of which latter neuritis of the supra-orbital, intercostal, and sciatic nerves are oftenest met. But "isolated neuritis of almost every cranial nerve has been recorded with such resulting conditions as optic atrophy, loss of smell and taste, ophthalmoplegias, both internal and external, oculo-motor, facial, bulbar and pseudo-bulbar palsies of various types, including true pneumogastric paralysis" (Mills).

Lepto-meningitis (pia-arachnoid) and cerebro-spinal meningitis are the commonest types of meningeal inflammations.

Bristowe has reported two cases of cerebral abscess, and has seen others in which the symptoms would justify such a diagnosis.

Convulsions have been repeatedly observed, and, in a few instances, the epileptic habit has been permanently established. Mills has seen two cases.

Polio-myelitis anterior is the form of spinal cord disease most frequently associated with influenza. Temporary paralysis of one or more limbs, evidently of spinal origin, is occasionally seen. Abolition of the patellar reflex has been noted.

Neuralgic attacks, severe, persistent, and involving any of the nerve-trunks are, perhaps, the commonest of the post-influenzal neuroses. The rekindling of old and fading neuralgias during convalescence is another of the curious features of the disease.

Neurasthenia, both cerebral and spinal, hysteria and hystero-epilepsy, with their illimitable repertory of disease mimicries, were frequent sequels in the late epidemics.

Insanity is not rare. It usually takes the form of melancholia, with hypochondriacal or religious delusions and decided suicidal impulses. Leledy, Ladame, and others believe that influenza may act either as an exciting or as a predisposing cause, but that there is always an antecedent acquired or inherited predisposition. The onset is often sudden and bears no relation to the severity of the febrile attack. The insane are less disposed to contract grippe than the sane, and its occurrence is sometimes attended by a remission in the mental symptoms. Althaus also recognizes as a rare post-grippal neurosis a peculiarly rapid—galloping—form of general paralysis of the insane, of which he has seen a few examples.

Biermer, Gottschalk, and others remark upon the frequent occurrence of severe hemorrhagic endometritis. In these cases the uterus is enlarged and sensitive, and the hemorrhage profuse. It has long been known that women sick with influenza were subject to profuse and painful menstruation, and, on the other hand, that the menses were apt to return to those suffering from amenorrhœa. Pregnant women are liable to abort under the same conditions.

Prognosis.—Uncomplicated cases of influenza recover. The prognosis is modified somewhat by the character of the prevailing epidemic and the physical condition of those affected. The extremes of life and those debilitated by disease or vicious habits bear influenza badly. Infants are fortunately less likely than adults to contract the disease. The mortality is largely due to complications or to its development in those suffering from advanced pulmonary, cardiac, or renal affections.

Diagnosis.—Influenza is not likely to be mistaken in its epidemic form. The numbers affected, the fever, the catarrhal phenomena, the prominence of the nervous symptoms, and the rapid course will readily establish the diagnosis. Influenza bears a striking resemblance to non-specific catarrh caused by atmospheric changes, but it is only in those isolated cases which herald the approach of an epidemic that this similarity could mislead.

The only difficulty in diagnosis attaches to those cases occurring during the prevalence of an epidemic of grippe in which coryza is absent and the symptoms are those of a general fever. Some of these cases bear a striking resemblance to typhoid fever. The continued fever, delirium, epistaxis, diarrhœa, and prostration are common to both, but the temperature charts and progress of the diseases are very dissimilar.

In other cases the suddenness and violence of the on-

set, the variety and intensity of the nervous symptoms, and the irregular febrile movement are very like epidemic cerebro-spinal fever.

Dengue and the nervous type of influenza have many symptoms in common, but the former is preëminently a disease of tropical climates. In our own country it is confined to the Gulf States and rarely extends beyond the thirty-second parallel. Only once (1780) has it reached as far north as Philadelphia. It was at that time described by Dr. Rush under the name of bilious remitting fever.

TREATMENT.—Influenza is a self-limited disease of short duration. There is no specific and the treatment is largely symptomatic. In view of the many severe complications and sequelæ which may arise, every case should be regarded as serious enough to necessitate confinement, at least within doors, until the fever has disappeared. The experience of the late epidemics demonstrated that those who remained in bed from the beginning of the illness not only appreciably shortened the attack but made a pleasanter convalescence.

Rest in bed, a mild calomel purge or saline draught, cooling drinks, an occasional Dover's powder to quiet cough, and the employment of such general hygienic and dietetic measures as are indicated in acute infectious diseases will meet every indication in simple, uncomplicated cases.

In the futile search for a specific all of the leading remedies, new and old, received an extensive trial in the recent epidemics. The coal-tar derivatives—acetanilid, antipyrin, and phenacetin—were all extensively used, but phenacetin, from its greater safety and the absence of unpleasant after-effects, deservedly enjoyed the greatest popularity. Given early in the attack, it rarely failed to relieve the headache, lower the temperature, and lessen the muscular soreness and tired feeling. The writer obtained excellent results from its combination with quinine or salol and caffeine.

Salicin is an eligible remedy. It acts as a mild tonic, reduces temperature, excites perspiration, and relieves the gastro-intestinal irritation. Its taste is objectionable. Quinia in medium-sized doses may be advantageously given throughout the sickness but is especially indicated in the later stages and in delayed convalescence. When the head pain and muscular soreness are prominent the salicylate of cinchonidia is preferable to quinia, and is supposed to possess decided prophylactic powers. The insomnia, as a rule, readily yields to the bromides or chloralamid. The singularly depressing effects of grippe on the mental and physical powers strongly contraindicate the use of lowering measures and remedies. Stimulants, preferably some form of ammonia or alcohol, should be resorted to on the first evidence of failing strength. In the presence of great thoracic distress or heart-failure a timely use of the heart tonics, of which digitalis and caffeine are the best representatives, may avert the threatened danger. Strychnine alone, or in combination with tonics, is the most reliable drug with which to tone up the feeble heart so often left by grippe.

Gastro-intestinal irritation is best met with salicin, bismuth, resorcin, and the salicylates.

Local applications to the inflamed mucosa add greatly to the patient's comfort and favorably influence the course of the disease. In the writer's experience nothing gives such grateful relief as the occasional spraying of the throat and nose with a weak solution (one to two per cent.) of cocaine and menthol in benzoinol. A gargle of boracic acid or salicylate of soda in glycerine and water soothes the irritation of the mouth and throat. Dobell's solution in the form of spray, or the inhalation of steam, pure or medicated, with eucalyptus, creasote, or terebene, is of signal benefit in allaying the laryngeal and bronchial irritation. Troublesome cough is readily controlled by the old-fashioned Brown's mixture, or by small doses of codeine in syrup of wild cherry.

In the graver types of influenza, or when the course is anomalous, care must be taken not to overlook complications, which often, especially those of intra-thoracic origin, steal on insidiously. These must be managed according to the principles of treatment laid down on other pages of this HANDBOOK.

Delayed convalescence will call for a prolonged course of tonics, and, in many cases, for a temporary change of climate.

Little has been attempted in the way of prophylaxis. It has, however, been lately proposed, on account of its probable contagiousness, to isolate those suffering from the disease and to close the schools and places of public resort during an epidemic.

But the volatile nature of the pathogenous material and the remarkable rapidity with which influenza spreads—its whole career from inoculation to full development being only a matter of hours—will doubtless render abortive all attempts at quarantine.

It has been abundantly proven that during the prevalence of the epidemic influence those who are overfatigued or much exposed in the open air, especially at night, are more susceptible to the disease. The lesson to be drawn from this fact is obvious and should be heeded by the aged and debilitated.

Considerable testimony has been recently collected to show that vaccination with animal lymph furnishes immunity against influenza. Dr. Goldschmidt, of the Island of Madeira, was the first to call attention to this fact. The island suffered from a double invasion of small-pox and grippe, and in investigating the relationship between the two diseases he ascertained that out of 112 persons successfully revaccinated not one contracted influenza; and of 98 in whom revaccination was attempted but failed, only 15 showed any symptoms of the disease. In an isolated villa there were 27 inhabitants, of whom 12 had been recently vaccinated. These all escaped, but the 15 who had not been vaccinated were affected. Althaus, who strongly advocates the protective power of vaccination, refers to illustrations which came to his knowledge, in which small clusters of recently vaccinated persons remained untouched, although surrounded by and freely mingling with grippe-stricken people. The well-known immunity of children is likewise attributed to the protective influence of vaccination. It is stated that in the German army, where revaccination is systematically enforced, influenza was less prevalent and less fatal than in civil life. While influenza affected forty-two per cent. of the population of Berlin, and about sixty-four per cent. of that of Paris, its prevalence in the German Army amounted to only a little more than eleven per cent. A number of garrisons were entirely spared while the inhabitants of the adjacent towns suffered severely, and it is further stated that no garrison was ever affected with influenza when the civil population escaped. When an outbreak did occur in a military post it was found that those affected were almost exclusively soldiers who had not been recently revaccinated. And, finally, statistics show that the average duration of the disease is shorter, complications less frequent, and the death-rate lower in military than in civil life. Further developments in the prophylaxis of influenza will be awaited with interest.

INSANITY OF PUBERTY AND ADOLESCENCE.

The only addition of importance to what has already been said in the body of this work upon the developmental insanities, viz., climacteric and senile insanity and the insanity of puberty and adolescence, relates to the latter class. In fact, the pathology of the insanity of puberty has become a favorite study of late years through the growing recognition of the profound influence of the state of growth upon the rise, nature, progress, and future of mental disease in the individual.

Hereditary Influence.—We are largely indebted to Clouston for stimulating inquiry in this direction. He is now prepared to state very strongly, as the result of his experience and careful inquiries into family histories of individual cases in which there was an opportunity of obtaining reliable facts, that practically without exception the typical clinical case of adolescent insanity (of the kind described, for example, on p. 128, Vol. IV., of this HANDBOOK) has in his or her ancestry, immediate or collateral, one of the following neuroses, in the following order of frequency:

1. Insanity.
2. Neurotic instability.
3. Intemperance amounting to dipsomania.
4. Epilepsy.
5. Hereditary tuberculosis.
6. General diseases of the nervous system.
7. Congenital imbecility or idiocy.

He finds such hereditary predisposition in forty-five per cent. among adolescents, while but twenty-three per cent. of other cases are thus handicapped.

Our division of the insanities of puberty and adolescence into several groups, according to the various manifestations of mental disease in this transitional epoch, viz., the genuine hebephrenia of Hecker, stupor, hysterical, and masturbatory insanity, receives support and further development in a comparatively recent investigation of the insanity of puberty by Mairet, particularly in the matter of stupor, which, as we have pointed out, occurs almost exclusively in adolescents.

Stupor.—Clinical observation shows, he finds, that puberty can give rise to insanity, and that the insanity of puberty has not always the same clinical signs. Accordingly this form may be subdivided into insanity of puberty with arrest of intellectual development, and simple insanity of puberty. The latter may appear under several different forms: Melancholic stupor, choreic mania or maniacal chorea, impulsive mania, and hysterical mania.

The form of stupor which he describes as peculiar to puberty is identical with stuporous insanity (so-called acute dementia), as distinguished from true melancholic stupor, and merits more ample description than we have accorded it.[1] In three out of seven cases Mairet found puberty to be the sole predisposing cause, while its action was favored in the remaining four by hereditary predisposition. The sex also plays a conspicuous rôle in the causation, as most of the subjects are females. Onanism and mental overwork are occasional factors. Sometimes there is no apparent cause, the stupor appearing suddenly and unexpectedly. A common exciting cause is a moral one, such as crime or other disgrace.

There is usually a prodromic period marked by a variety of nervous and general symptoms, chiefly chlorosis and irregular menstruation in girls, and by physical fatigue, palpitations, and cerebral hyperæmia in men. The onset of the stupor of puberty is usually sudden, and in most cases is manifested by hallucinations, ideas of fear, and intense maniacal excitement. Sometimes these symptoms are accompanied by fever of an ataxo-dynamic character. Rarely, stupor itself begins the attack. Hysterical manifestations may also appear before or with the excitement. Ideas of grandeur may take the place of those of fear. The early physical symptoms are refusal of food, sordes, dry tongue, and constipation due to rapid exhaustion. The circulation is poor, and sometimes sensation is much diminished. This period lasts but a short time, sometimes only a few days, but generally several weeks, to give way to a new phase which is the essence of the disorder, *stupor*. The change is usually gradual, the hallucinations slowly disappearing, and the stupor growing more profound. The patient stands motionless wherever he may happen to be, the head bent, the arms hanging limp. The saliva escapes from his mouth, and his evacuations are passed involuntarily and unnoticed. All food is refused and there seems to be no sensation of hunger. The patient answers no questions and cannot be aroused. That he feels and even hears is sometimes evidenced, however, by his turning his head to the questioner. The circulation is retarded, the heart-sounds clear but feeble, and the pulse more or less rapid, small, compressible, and excitable. The extremities are cold and, perhaps, œdematous. The temperature is below normal. Menstruation is suspended. Sensation is much diminished, but not abolished. The general and cerebral nutrition is lessened. Although thus plunged in stupor, the patient may suddenly have an attack of excitement. Oftentimes this is limited to violent laughter, lasting ten minutes or a quarter of an hour, without any apparent knowledge on the part of the patient why he does so. At other times the disturbance is more general, and then the patient will cry, repeat monotonously the same words, or more often the same sounds, to dance, etc., while the dull, heavy condition persists. Other patients perform ridiculous acts, such as swimming movements, contortions, etc., or else they suddenly throw themselves upon others and beat them, and soon fall back into stupor. These attacks are produced quickly and are of short duration, from a quarter of an hour to an hour, to reappear after a time. The period of stupor, the principal feature of the disorder, lasts from several weeks to as many months. It is a most favorable form of insanity in respect to recovery, which takes place gradually as a rule. It is impossible to confound this with any other form of mental alienation. It is sometimes distinguished with difficulty from the melancholy, with stupor of older patients, but differs therefrom chiefly in the severity of the onset and the rapidity of the emaciation.

CHOREIC INSANITY (OR "MANIACAL CHOREA.")—The insanity which accompanies acute chorea also belongs to this period of life, is of pubescent or adolescent nature, and belongs exclusively to the group under consideration. All the cases of insanity associated with acute chorea on record have occurred within the pubescent and adolescent period, between the ages of thirteen and twenty-three. Most of them have the mental or nervous predisposition, inherited or acquired, so common in the insanity of puberty, and all of them, as a rule, have manifested one or other of the physical ailments common to this critical period, viz.: anæmia, chlorosis, scanty menstruation, pallor, palpitation of the heart, headache, etc. It is now generally recognized that chorea in some form is almost invariably associated with mental changes varying from simple impairment of memory, unusual and extensive irritability, etc., to acute mania or dementia. It is equally a fact that chorea is in its most developed state at this period, and that the accompanying mental manifestations are most marked and peculiar, the severe, dangerous, and fatal cases occurring then. It is also noticeable that in almost every case the choreic and mental symptoms appear and subside at about the same time, thus giving proof by evolution also of the close alliance of the two diseases. This intimate union can only be explained by community of origin, chorea and insanity being two independent branches from the same trunk. Consequently, when we find chorea, essentially a disease of growth, intimately

united in youth with mental disorder, the pubescent nature of that insanity is evident. As the acute forms of both disorders do not appear *together* at any other time of life, choreic insanity, or maniacal chorea, plainly belongs in the category of insanity of puberty and adolescence.

The choreic form of adolescent insanity is more common in the male sex, and heredity plays a more prominent part than in the other varieties. Of the prodromic period cephalalgia is the most frequent and important symptom. Irritability and mental confusion, or change in disposition and insomnia, are present.

The onset is generally abrupt, following close upon the exciting cause. Usually the choreic and mental symptoms appear at about the same time—either the chorea precedes the psychical trouble, as in a case reported by Thore, or the psychical change takes precedence, of which the case to be described later is an example. With the onset may appear delusions or hallucinations which may later dominate the scene. In our case the peculiar nature of the initiatory excitement shows their presence, although none were expressed. Insomnia and nightmare are common. Fever is not an uncommon accompaniment at this stage. The chorea, whether general or localized, reaches its height early in the attack, which is usually not the case with the insanity. The choreic movements also are almost invariably increased during the mental agitation.

The next and principal stage is that of choreic mania, which may be either simple or hallucinatory. The maniacal condition is the same, as a rule, as that of ordinary mania, except perhaps for its marked irritability. The patient may become readily aggressive even when not excited, or, as in our case, he may present a marked condition of hebetude and mental incoherence. These patients are at times, like others of the adolescent class, poetical and dramatic in speech and writing, as well as vain and declamatory. The attacks of agitation in the more marked and characteristic cases consist in running, jumping, leaping, shouting, nightmares, etc. They are also apt to be especially destructive and homicidal. These attacks are almost always spasmodic and impulsive, and are sometimes followed by a state of mental and bodily weakness. Sometimes the attacks are not prompted by hallucinations, as is evidenced by the accounts given by recovered patients; but as a rule they spring from hallucinations and delusions chiefly of the nature of fear.

The duration of acute choreic insanity is very variable, usually several months, but occasionally it lasts as many years. One of Mairet's cases recovered in four years.

The prognosis is comparatively good, but less so than that of the stupor of this period, perhaps because the hereditary predisposition is greater in this form. The following case presents most of the usual features of the disorder, but the severe motor symptoms so far predominated as to mask the mental manifestations, and perhaps even to take the place of, or prevent, the characteristic maniacal outbursts. It properly belongs, as we have said, to the other class, represented by the cases whose condition is that of hebetude and mental incoherence.

W. W——, married, twenty-three years of age, was admitted to the West Riding Asylum February 18, 1882. The certifying physicians stated that the patient was a violent lunatic and gave the following facts: 1. "Talks incoherently, taking no notice of any questions put to him." 2. Relatives report that, "he will sit for hours without speaking." The family physician stated: "He is by nature eccentric in his habits and inclined to be self-willed. Just before the attack he became depressed in spirits, irritable and suspicious of those about him. During the attack he was sometimes violent, sometimes depressed, but had lucid intervals; raved indifferently on various subjects, and would strike with great violence indiscriminately." The patient was brought to the asylum securely bound in a strait-waistcoat which was reinforced by heavy leathern straps. As soon as he was freed from restraint he was seen to be suffering from severe chorea. He was placed in a padded room and became much quieter.

Previous History.—Nothing satisfactory to be learned as to hereditary predisposition. No personal history of convulsions or rheumatism. Had been rather delicate, and had an attack of pleurisy with inflammation of the lungs several years before. His domestic circumstances had been satisfactory. Just before and ever since his marriage, six months before admission, he had worked very hard at his trade, carving and gilding. About four weeks before admission he was obliged to leave his work on account of severe continuous and general cephalalgia, which confined him to bed for two weeks. At this time alteration in his manner and conduct became for the first time noticeable. He was dull, preoccupied, and reticent, appeared dazed and indifferent to his condition and surroundings. Later he returned to his work and seemed "like himself" in every way. A week later he returned home in a confused state of mind and soon became delirious. For the next two days he was much excited, refusing to go to bed or to take food, threatening to throw himself out of the window, and weeping at trifles. No hallucinations or delusions appear to have been expressed. Just after the excitement became pronounced he began to wriggle about, contort his face, protrude his tongue, etc. This disturbance subsided in a day or two. He then conversed freely and naturally, and said that he had fallen in attempting to board a horse-car just before his attack came on, but did not meet with any injury; that he then became confused and wandered about the town a long time before he could find his home. Three days before his admission, when supposed to be rapidly convalescing, his former condition returned with renewed intensity, being ushered in by rapid and disconnected talk. From this time he became very unmanageable and his movements so energetic that he was with difficulty prevented from falling out of bed. His knuckles and elbows were also abraded from contact with the wall. He showed at this time no disposition to violence.

Physical Appearance.—Pale and emaciated. Pupils dilated, the right excessively so and only slightly responsive to light. All his voluntary muscles appear to be affected with chorea. He incessantly writhes and plunges about the bed, tosses his arms, clinches his fists, contorts the face, etc. Abrasions on knuckles and elbows. Skin over sacrum reddened, and on the tongue an ulcer, a quarter of an inch in diameter, caused by biting. Pulse, 140, and of fair strength. Heart and lungs normal; appetite fair. He passes his evacuations in bed.

Mental Condition.—Though questioned in an interval of comparative calmness, the patient can evidently make nothing of what is said to him. He is ignorant of where he is, why he is here, how long he has been here. He makes incoherent, nonsensical replies to the simplest questions, but protrudes his tongue when asked. Expression lost and wondering. During sleep there have been slight movements of the upper extremities and head occasionally.

February 23d to 26th.—Distinct improvement on the whole. The choreic movements are now absent during sleep. By day he is occasionally quite still, and although there is at present much movement of the head and facial muscles, he has been quite free from spasm. A small eschar has formed over the sacrum, and the abrasions on the elbows and hands are inflamed. Is fed by the attendant with soft food, but has great difficulty in properly masticating it. Still irrational and incoherent. He talks in a whisper as if conversing with someone, and most disconnectedly. Says he is in "Fletcher's Mills."

March 4th.—He is not still a minute at a time, but the movements are now confined to the face and upper extremities. He talks in a low tone most of the time. Occasionally he jerks out a sensible reply after evidently trying to collect his thoughts, but soon wanders off onto a variety of subjects.

March 8th.—He is quieter, but still scowls and rolls about somewhat. Touching any part seems to excite muscular contraction. Still unable to concentrate his thoughts or to keep them in the right channel, just as he fails to direct his muscular movements properly after

making a good beginning. He can tell the time and answer simple questions, when roused and made to apply his mind. Still passes his evacuations in bed. Bedsore deep.

March 11th to 19th.—There is but little mental improvement, although the patient is generally free from morbid movements. He often starts up and looks about him, muttering disconnectedly. He replies to a simple question: "They were laughing at me—either jump over here or over there." Allows the medicine to drool from his mouth without attempting to swallow. Gives an occasional rational answer after much pressing. Still unclean in his habits.

March 26th.—The patient has been for some time entirely free from choreic movement. Sits up most of the day. Has become clean in his habits. Whole expression brighter. Answers simple questions correctly, but not readily. Still starts wonderingly when addressed, and makes strenuous but vain attempts to understand and reply. A fortnight later the patient had, in great measure, recovered his intelligence. He recognized his surroundings and that his mind had been deranged. His memory had become nearly restored, but he was still confused and wandering in manner, and his ideas were not perfectly coherent. Expression rather perplexed and vacant. Was still pale and thin. Appetite and sleep, excellent. Gait fairly steady. Bedsore healed. Three weeks later, he was discharged, recovered. There was some elevation of temperature during the three weeks immediately following his admission, but never rising above 101.3° F.

It is well in conclusion to re-group the insanities of this period, giving precedence to more characteristic varieties, as follows:

INSANITIES OF PUBERTY AND ADOLESCENCE.

Pure Forms.

Occurring only in youth and essentially of the adolescent type.	Hebephrenia. Acute Choreic Insanity. Stupor.

Mixed Forms.

Occurring usually but not exclusively in young people.	Hysterical Insanity. Masturbatory Insanity.

The reader is referred to the contributions of Mairet[2] to this subject, from which we have quoted in this article, as well as Clouston's exhaustive lectures on the "Neuroses of Development," for further study of this subject.

Henry R. Stedman.

INSANITY, THE PHYSICAL EXPRESSION OF.

I. INTRODUCTORY AND RETROSPECTIVE.

Francis Warner has defined expression to be "the outward indication of some inherent property or function." All outward muscular movements, whether of the face, trunk, or extremities, succeed definite functional activity of some portion of the central nervous system. This larger use of the word expression is comparatively recent. Muscular movement as an index of cell activity within the encephalon is the latest advancement that physiognomical science has made. Viewed in this light, physical expression deserves serious study. Particularly does the physical expression of the insane merit investigation, for it must be presupposed that any disturbance of function in the central nervous mechanism would be quite likely to be reflected in perverted muscular movement at the periphery.

Previous to the present century study of physical expression was limited to the face. Now, while it is true that the expression of the emotions receives its most perfect and frequent demonstration in the facial region, it must not be forgotten that the entire muscular periphery is likewise a participant. The same physiological processes underlie the manifold, subtle, and delicate movements of the facial muscles as well as the more palpable movements of the muscles of the trunk and extremities. The physiological basis of the gesticulations accompanying ordinary conversation, as well as the more finished gestures of the orator, is undoubtedly the same. All explorers among barbarous tribes give interesting reports of this language of signs. Stanley's observation of the gesticulations of the tribes in Central Africa, as well as the statements of the early discoverers and settlers of America, confirm this idea that there is a sign language common to all races of men. This in turn implies that the functional activities of the central nerve-mechanism are the same, both in savage and civilized races, and affords interesting proof of the unity of the human race.

Correct physiognomical knowledge, therefore, depends on a proper understanding of the physiology of the central nervous mechanism. Ignorance as to the functions of the brain and cord led the earlier writers into the most absurd interpretations. Even so shrewd an observer as Aristotle attempted to explain the physiognomy of man by a system of meaningless analogies. Fancied resemblances to wild animals, such as a broad expanse of chest and shoulders, and certain conditions of the hair and beard were supposed to indicate the possession of certain qualities of mind, such as bravery, energy, and the like.

It is not to be wondered at that the ancients, with their limited knowledge of physiology, should have entertained crude notions concerning the meaning of facial expression. Undoubtedly they were familiar with anatomy, but the subtle connection between the central innervating organ and the external muscular apparatus was entirely unknown to them. To have perceived in a general way that a certain cast of countenance was associated with a peculiar mental development was the utmost advance that their limited knowledge of animal physiology would allow. Hence, though they excelled in copying, they singularly failed in explaining nature. And, as is often the case, the domain that properly belongs to science was, through ignorance, relegated to charlatanism. Analysis of the human countenance was given over chiefly to soothsayers and magicians, who attempted no rational explanation of the various muscular movements of the face, but who pretended to read therein certain prognostications for the future.

It is interesting to trace the gradual development of physiognomic science from the earliest times to the present, and to notice how gradually correct physiological knowledge was attended by broader and more intelligent views as to the real meaning of physical expression. Nothing could be more absurd and childish than the vagaries of the ancient writers upon this subject, nearly all of whom either thought that expression was due to the mysterious influence upon the brain of certain abdominal vapors, or that the Aristotleian doctrine of resemblances gave the correct clue to the expression of the emotions.

Throughout the Middle Ages the study of the physiognomy became so identified with astrology and chirology as to lose even what loose scientific value it had previously attained. Mantegazza calls the seventeenth century the golden age of astrological physiognomy. "Then more than ever," he says, "did men have a passion for mysterious things, for mysteries which have a scientific appearance." The countenance and the heavens were mapped out, and not only character, but future events in the life of the individual were supposed to be prognosticated from a comparison between the lines of the face and the position of the stars in the sky.

G. B. Porta, of Naples, whose work "Della fisonomia dell'uomo" was published in 1627, did much toward severing the absurd connection between physiognomy and astrology that had arisen during the Middle Ages. He was nevertheless a strong believer in the doctrine of resemblances, and his comparisons of the heads of men with those of birds and lower animals are amusing illustrations of the extent to which a blind subservience to a theory may lead one. Notwithstanding the absurdity of many of his comparisons, he still deserves great credit as

being one of the first writers that attempted to trace a tangible relationship between the countenance and the mental and moral development of the individual. De la Chambre followed Porta in 1660, with his "L'Art de connaitre les Hommes," in which he showed a tendency to explain the countenance and its changes in a more rational way.

In 1747 James Parsons, M.D., delivered a short course in the Croonian Lectures on Muscular Motion. These were published in the Philosophical Transactions under the title, "Human Physiognomy Explained." This work, though quite short, is deserving of great praise, for it was a very sincere attempt at explaining facial expression in a more intelligent manner. He endeavored to refer the expression of the countenance to muscular movements in that locality, and by a series of plates sought to establish a relationship between the movements of certain facial muscles and specific states of mind. "The muscles," he says, "are the true agents of every passion of the mind, and the basis upon which our doctrine is founded." The soundness of his views is quite remarkable, and his essay is a prominent landmark in the progress of physiognomic science. The following quotation from his Lectures will meet with the approval of modern physiology: "First, every person has a particular bent or disposition of mind, which oftener reigns in him than any other; secondly, that this habitual disposition, causing the muscles of the face that are destined to express it frequently to act in obedience to that bent of mind, brings on at length an habitual appearance of that passion in the face, and moulds it into a constant consent with the mind. In the course of my own acquaintance, I know some persons who wear on their countenances a constant cheerfulness, complacency, and openness; and by experience I know it to be their continual disposition of mind; and on the other hand, I do know of some on whose faces a settled moroseness always strikes the beholder, and know it to be their own constant plague and that of those among whom they come."

After the appearance of Parsons's Lectures nothing of any especial worth was published until the year 1783, when Lavater, a Swiss clergyman, published his "Essays on Physiognomy Destined to Promote the Love and the Knowledge of Mankind." Lavater was an enthusiast on his subject, and it is remarkable that, being neither a physician nor an anatomist, he should have advanced views at once so much in accord with modern physiological and anatomical knowledge. He struck the keynote of a sound physiognomic science when he declared that outward expression was but the reflection of what was within, that it was the outward effect of an inner cause. He says: "There is not a living being which does not, at least after its manner, draw some inferences from the external to the internal; which does not judge concerning that which is not by that which is apparent to the senses. This universal though tacit confession that the exterior, the visible, the superficies of objects indicate their nature, their properties, and that every outward sign is the symbol of some inherent quality, I hold to be equally certain and important to the science of physiognomy."

Lavater, being a shrewd and acute observer, was not misled by mere resemblances to infer similarity of disposition and character. He recognized the incorrectness of the ancient method of comparing resemblances, and says, "What the great Aristotle has written on physiognomy appears to me extremely superficial, useless, and often self-contradictory, especially his general reasoning." Of Porta, the Italian physiognomist, he says: "He might more effectually have examined the excessive dissimilarity than the very small and almost imperceptible resemblances which can exist." And again: "It is singular enough that he has also compared the heads of men and birds. He speaks little concerning the horse, elephant, and monkey, though it is certain that these animals have the most resemblance to man." By recognizing the fact that the cranium bore some relation in size and external configuration to its contents, and that in proportion as one ascends the scale of animal life important modifications are met with in the size and shape of the skull, he tacitly admitted the relation between the cranium and the cerebrum, and the relationship between the development of the latter and facial expression.

In an article on "Medicinal Semiotics," Lavater suggests the influence upon expression of pathological conditions. Many physicians, from Hippocrates to his time, had accurately described the characteristic facies of disease, and yet few of them realized the physiological and pathological import of what they so faithfully described. Lavater, though not a physician, still inferred that the peculiar facies of different diseases suggests certain changed physiological conditions in the patients themselves. Lavater very nearly touched the true explanation of facial expression.

It is an interesting coincidence that while the Swiss clergyman Lavater was writing his views of physiognomy, at nearly the same time, and in another country, the Dutch physician Camper was working out a theory of physiognomy in nearly the same channel. As might be expected, the physician and anatomist, from his knowledge of the different parts of the body and their physiological relation to each other, would be more likely to arrive at a comprehensive and exact theory than a layman. He clearly enunciated the correct physiological theory of physical expression when he said: "As dissecting of human bodies has been my constant occupation, I have had frequent opportunities of examining which of the nerves, communicating with these more active parts, must have been particularly affected; consequently which of the muscles must have been excited to action by these nerves; and from the action of these muscles depending upon their origins and insertions, course and connections, we may easily learn what pleats in the face, what kind of action in the hands, and so forth, they must necessarily occasion."

The next writer connecting the latter part of the last century with the present time is Sir Charles Bell, famous as the discoverer of the motor and sensitive nerves. Bell, by his accurate anatomical knowledge of the nerves, laid the foundation for all that has been written during the present century upon the subject of physiognomy. He first cleared away the confusion which had hitherto surrounded the anatomy of the cerebral and spinal nerves, and traced these nerves definitely to their terminations and origins. He demonstrated clearly the mechanism of facial expression. The physiology of reflex and automatic action, as well as the important functions sustained by the centres of the cerebral cortex, both in the motor and intellectual activities of life, had scarcely come to be understood in his day, otherwise he would have perceived that the causes of expression in man and the lower animals are often the same; that in each nervous energy is liberated from the cells within the central nervous mechanism, and subsequently transmitted along the nerve-channels to their terminations in muscular structure; that the difference between the causes of expression in man and the lower animals is really less than he imagined, being a difference in degree rather than in kind, and due rather to complexity of structure attained in the cerebral cortex of man.

Dr. G. B. Duchenne's "Mechanism of the Human Physiognomy," published in 1862, was an ingenious and interesting attempt to demonstrate the mechanism of facial expression. By the aid of the two poles of a battery Duchenne sought to isolate certain facial muscles, and by causing them to act independently of the others, produce artificially the expressions caused by the natural action of these same muscles. It seems questionable, however, whether the action of the electric fluid upon the nervous filaments in the face is precisely similar to the action of the nervous centres within the brain upon these same nervous and muscular tracts. In fact it is very doubtful whether the action upon the muscular periphery of the feelings, such as grief, joy, disgust, and the like, is of the same quality and intensity as that produced by the cells of a galvanic battery. Again, it is very questionable whether the actual results which he has shown in a series

of photographs are faithful representations of the various states of mind ascribed to them. The field is one in which the author's imagination may very easily lead him astray. Having formed a preconceived idea of what a certain artificially produced expression may mean, it is very easy to recognize that particular expression. But one who has not previously read the author's description of the plate may, as Darwin says, very easily conceive it to mean something else.

Pierre Gratiolet's lectures, delivered at the Sorbonne, and published in 1865, were a valuable addition to the subject, and particularly interesting because they were the first contribution recognizing that physiognomical changes were only a part of a wider series of muscular movements in other parts of the body. Previous to the appearance of these lectures all writers upon the physiognomy limited their studies to the facial region, but Gratiolet saw that muscular movements of other parts than the face entered into expression. In his "De la Physiognomie et des Mouvements d'Expression" he says: "The face is not the only portion of the body capable of expressing the feelings; on the contrary, the hand, the foot of man and animals, the tail of certain carnivora such as dogs and cats, have expressions that cannot be misunderstood. We may add that there is no movement that does not represent expression and follow the laws of expression."

In 1872 was published Darwin's "Expression of the Emotions in Man and Animals." Darwin, with the clear insight of the naturalist, fully recognized the meaning of facial expression, or more properly, physical expression. Both in man and the lower animals he perceived that the various muscular movements of expression, whether occurring in the face or in the extremities, were merely the outward reflection of interior states of the central nervous system. His wonderful acquaintance with animal life, reinforced by the vast amount of material accumulated during his busy life, makes his work an exceedingly interesting and instructive one. As Mantegazza says, "with his large and comprehensive spirit he traced the general laws which govern expression in the entire animal kingdom. His work is one of the most splendid monuments raised by his genius, and one can say without exaggeration that expression, as far as it is a special branch of comparative biology, was established as a new science only in the work published in 1872."

In 1885 was published "La Physionomie et les Sentiments," by Mantegazza, and in 1886 "Physical Expression," by Dr. F. Warner. Both volumes are a fitting conclusion and summary to all that had previously appeared upon this subject, and a pertinent introduction to the various modifications of physical expression in insanity. A clear understanding of the mechanism of physical expression and close observation of the insane, demonstrate the physiological laws of cause and effect underlying the remarkable changes in expression that occur in various stages of insanity.

II. The Mechanism and Physiology of Expression.

In man the central nervous system has reached its highest development. Beginning with the lowest and most rudimentary forms of animal life, a single centre with afferent and efferent nerve-tracts leading to and from the muscular periphery, is typical of nervous structure throughout the animal kingdom. Becoming more and more complex as we ascend the scale of animal life, in man this nervous structure attains vast complexity. In him the central nervous system is composed of intricate series of cells connected with each other, layer upon layer, the areas above being connected with those below, and so specialized that different areas have specific functions, and yet all subject to control of the cortical gray matter.

Three factors enter into the Mechanism of Expression:

I. The storage and discharge of nerve-force from the central nervous system.

II. The power of inhibition possessed by the cerebral cortex.

III. The trophic changes consequent upon the processes of waste and repair that are constantly occurring in the cerebral cells.

I. *The storage and discharge of nerve-force from the central nervous system.* Physiological and anatomical data lead to the conviction that the mysterious property known as *nerve-force* or *energy* is in some way identified with functional activity of the cerebral cortex, and that, after leaving the cortex, its route is downward to the corpora striata and thence onward through the crura, the corpora quadrigemina, the pons varolii, and the medulla to the peripheral muscles. However it may be modified by the structure through which it passes, there is little doubt that this is the route. Exactly what this nerve-force is would be difficult to say. It is undoubtedly a form of energy, and the nervous system is the special region in which its manifestations may be studied. In some respects it is singularly analogous to that mysterious energy which is now being utilized in manifold ways in the daily life of mankind. Like the electrical fluid, it is invisible and realized rather by what it accomplishes than by any recognizable attribute.

The cortex cerebri seems to be the goal to which are referred all sensations received from without through the various channels of sense. Such sensations are gathered up by the different expansions and terminations of innumerable afferent nerve-filaments in the organs of special sense, like the eye and ear, or in the infinitesimal fibres of the nerves of touch in the skin, and are passed on through various afferent nerve-tracts to the ganglia in the optic thalami, where they are in some way modified and transferred to the cortex, there to serve as stimuli, not only to higher intellectual action, but to the generation of nerve-force. The cortex is, therefore, the objective point toward which all sensations received from without are directed. It is undoubtedly the seat of all intellectual processes and the great reservoir of nerve-energy.

However imperfectly we can define this nerve-force, there is no doubt that it conforms to the law of "Conservation of Force or Energy," which is recognizable everywhere in the great natural world about us. In accordance with this well-known law, either the energy, force, or whatever we may choose to call it, will remain stored up as potential energy, or it will be distributed and appear in some more active form as motion. Ganot says: "When the form of a body is changed by the action of forces, either the work done against the internal forces will remain stored up as potential energy, as in a compressed spring, or will have been replaced by the development of an equivalent of heat. Now, this being premised, we see that the energy communicated to any body, or system of bodies, is withdrawn from some fund of energy previously existing; thus, the energy communicated to the piston of a steam-engine is withdrawn from the heat of the steam; we also see that of the energy thus communicated none is destroyed, but is merely distributed, and exists either as potential energy or as motion of the bodies acted upon, or has been replaced by an equivalent of heat. This fact is called the conservation of force, or more properly, the conservation of energy" (Ganot: "Elementary Treatise on Physics," p. 40). In accordance with this same law the actual forces in the world about us, such as the waves of light and sound, and the ponderability and resistance of bodies with which we may come in contact, all these natural forces are transmitted to the cortex through the various channels of sense; there they are not lost but merely transformed into potential energy, which either remains stored up in the delicate nerve-centres of this region, or, on being liberated and distributed along different efferent routes, appears at the periphery as muscular movement. The comparison with the storage of steam within the boiler is not inapt. Such an accumulation of force must be relieved. In the case of the boiler, the steam, which represents the force, must be liberated at the safety-valve or converted into heat or power; and, in the case of the brain, the potential energy received through the various sensory channels must seek relief through the different

efferent outlets which have their termination in the muscles. Hence muscular movement, in other words, physical expression, is the one universal method by which the higher brain-cells are relieved of their stored energy.

Darwin thus admirably describes this generation and liberation of nerve-energy:

"A sensitive nerve when irritated transmits some influence to the nerve-cell whence it proceeds; and this transmits its influence, first to the corresponding nerve-cell on the opposite side of the body, and then upward and downward along the cerebro-spinal column to other nerve-cells, to a greater or less extent, according to the strength of the excitement; so that, ultimately, the whole nervous system may be affected. This involuntary transmission of nerve-force may or may not be accompanied by consciousness. Why the irritation of a nerve-cell should generate or liberate nerve-force is not known; but that this is the case seems to be the conclusion arrived at by all the greatest physiologists, such as Müller, Virchow, Bernard, etc. As Mr. Herbert Spencer remarks, it may be received as an 'unquestionable truth that, at any moment, the existing quantity of liberated nerve-force, which in an inscrutable way produces in us the state we call feeling, *must* expend itself in some direction—*must* generate an equivalent manifestation of force somewhere;' so that, when the cerebro-spinal system is highly excited, and nerve-force is liberated in excess, it may be expended in intense sensations, active thought, violent movements, or increased activity of the glands. Mr. Spencer further maintains that an 'overflow of nerve-force, undirected by any motive, will manifestly take the most habitual routes, and, if these do not suffice, will next overflow into the less habitual ones.' Consequently the facial and respiratory muscles, which are the most used, will be apt to be first brought into action; then those of the upper extremities, next those of the lower, and finally those of the whole body."

The cortex is therefore quite constantly excited by the various stimuli transmitted to it from the ganglia of the optic thalami, and just as constantly is it sending forth activities through innumerable efferent nerve-channels to the ganglia of the corpora striata, there to be newly arranged and organized before being transmitted to the tracts at the base of the brain and thence to the various muscles. The cortex, therefore, plays a most important part in all the motor activities of life. It is the great storehouse of nerve-force, as well as the seat of all intellectual action. In a certain sense the brain is a great reflex organ; it is continually receiving stimuli from without, which act as excitants to its various centres, and these centres, in obedience to the stimulations received from without, are constantly discharging nerve-energy which may be measured and realized in the countless motor activities that go to make up the life of mankind. Nerve-energy is in part, therefore, measured by muscular activity. And thus physical expression becomes one of the important agencies by which we estimate the nerve-force and vitality of the individual. It will be interesting subsequently to observe how normal and healthy physical expression is perverted by the various functional and organic conditions of the brain in insanity.

This discharge of nerve-force from the brain is either voluntary or involuntary. All the muscular movements that enter into the daily life of man come under one class or the other. It is needless to enter into the much-discussed question as to whether independent motor centres exist in the anterior convolutions of the cortex. The important fact to be remembered is that nerve-force passes down from the cortex to the corpus striatum, and whether it is essentially motor in character before or after it leaves the cortex or corpus striatum, the route followed by it from the cortical centres to the peripheral muscle is always downward through the structures mentioned; and another interesting fact is that automatic and habitual movements become retained, or *organized*, as the physiologists say, in the corpora striata. It is now considered that all the ordinary movements of daily life, such as walking and the like, and many muscular movements of complex character which have been acquired by hard and constant application, are at last permanently organized in the corpora striata, so that, by a single effort of the will, their easy and almost unconscious performance may be elicited.

Many purely reflex, as well as acquired, muscular movements are undoubtedly effected through the action of the optic thalami and the corpora striata without once calling upon the higher centres in the cortex. Sensory impressions are received in the centres of the thalamus, and excite into activity certain centres in the corpus striatum, and, as a result, certain muscular movements ensue. Such movements are purely reflex and automatic, and are often independent of volition and consciousness. Undoubtedly this purely automatic action of the basal ganglia, entirely independent of the cortical centres, is of more common occurrence among the lower animals than in man. Still there are many instances on record now to prove that many most complicated acts have been performed by men at a time when their consciousness and volition—in other words, the centres in the cortex—were entirely in abeyance or quiescent.

On this point Ferrier says: "In man, however, the shorter circle through the optic thalami and corpora striata does not appear sufficient, for the interruption of the conscious circle through the hemispheres by lesion of the cortical motor centres produces paralysis of a very complete and enduring character.

"This goes far to show that even the most habitual, or even the most automatic, actions of man require the co-operation of the centres of conscious activity, a view which is taken and strongly argued by Dr. Ireland.

"But though the basal ganglia may not, of themselves, suffice for the execution of the habitual movements of man, there is every reason for believing that they do so to a large extent, from the fact that the performance of habitual actions exercises but little interference with the conscious activity of the hemispheres in other directions.

"We may express it thus, that in actions requiring conscious discrimination and voluntary effort the larger circle of the hemispheres is involved, but that in the actions which have become habitual and automatic the larger circle is greatly relieved by the organic nexus between impression and action which has been established between the sensory and motor basal ganglia. The optic thalami and corpora striata form thus a sensory-motor mechanism, according to the views of Dr. Carpenter. I would use the term, however, only in the generic sense of afferent-efferent, it having been shown that sensation, or consciousness of impressions, is not a function of the optic thalami. Hence the reaction between the optic thalami and the corpora striata, being below the domain of consciousness, is outside the sphere of psychical activity, properly so-called" (Ferrier, "Functions of the Brain," chap. x.).

Just as the ordinary habitual movements of daily life become organized in the corpora striata and only await the proper stimulus for their elicitation, so has Ferrier advanced the theory that the co-ordination of sensory impression with the mechanism of emotional expression is situated in the corpora quadrigemina. He says: "The foregoing considerations on the relations between the phenomena of irritation and destruction of the corpora quadrigemina, though in many respects professedly of a hypothetical nature, tend to support the view that these ganglia are the centres specially concerned in the reflex expressions of feeling or emotion. This is rendered still more probable by the recently demonstrated influence which the corpora quadrigemina, or, more properly, the deeper parts of the corpora quadrigemina, exert on the functions of circulation and respiration, modifications of which are one of the most frequent concomitants of states of feeling or emotion" (Ibid., chap. v., p. 83).

It is worthy of note also that the third and fourth pair of cranial nerves, as well as the sensory roots of the fifth pair, have their origin in the corpora quadrigemina. All these nerves play a certain part in facial expression. The third nerve, both by its action on the muscles of the eye-

ball and by its connection with the iris, exerts a more or less prominent influence on the changes of facial expression. In like manner the fifth nerve, though chiefly sensory, still by its motor distribution to the pterygoid, masseter, and temporal muscles, is in some degree influential in certain pathological states of expression.

Chief among the factors in physical expression, and particularly in facial expression, is what physiologists have called *muscular tonicity*. It is that condition of the muscles by which a continuous, normal tension is maintained, and is undoubtedly due to the constant transmission of nerve-force from the cerebral centres through various efferent paths to the muscular periphery. This particular discharge of nerve-energy is purely involuntary, and is not recognized in the individual consciousness. Duchenne, in his "Mécanisme de la Physionomie humaine," speaking of *tonicité musculaire*, says that this force never sleeps, that it never ceases, except at death, and that by means of it that equipoise and natural equilibrium of the facial muscles is kept up which constitutes the natural and distinctive physiognomy of the individual. "It is thus," he says, "that the physiognomy in repose is established, the individual physiognomy which consequently ought to be the reflection of our habitual sentiments, the facies of our passions." Mantegazza, also, in "La Physionomie et les Sentiments," refers to this constant innervation of the muscles that enters so largely into healthy expression, and contributes to what he calls the *vivacity* of the muscles. "This vivacity of the countenance," he says, "is the signal that the nerve-centres are in the best possible condition." And again, "The good face, or the countenance of health, means that the physiognomy expresses a good general nutrition, an excellent chemical composition of the blood, and a powerful and well-balanced innervation."

Impairment of muscular tonicity is one cause of the changed expression among the insane. Organic and even functional disease of the cortex quite frequently impairs this transmission of nerve-force from the brain to the muscles which, as we have seen in health, should be constant, of uniform strength, and not intermittent. Our meagre knowledge of the pathology of insanity confirms the inference that *normal* muscular tonicity is produced by a certain constant action maintained by the higher cerebral centres upon the terminal muscular expansions; that the nerve-force is stored up in the cortical centres, and that it is undergoing continuous discharge and distribution to the innumerable deep and superficial muscles of the body.

II. *The power of inhibition possessed by the cerebral cortex.* Besides being a repository of nerve-force, the cortex undoubtedly exercises an inhibitory function, not only over its own centres, but more particularly upon those below them. The whole subject of inhibition is of great importance in any discussion of physical expression, and will be considered more in detail in the following chapter on the physical expression of the insane. Briefly, inhibition is the power of restraining nerve-function which one part of the brain or nervous system possesses over some other part. Many physiological and pathological facts suggest the idea that the chief inhibitory centres are located in the cortex. Study of the physical expression of the insane confirms this view.

In some diseased conditions central irritability is so great and the power of healthy inhibition so slight, that all manner of purposeless movements ensue. Chorea and certain states of mania and melancholia illustrate this. The irregular, spasmodic, and useless muscular movements that characterize these and other diseases of the central nervous system are due to the uninhibited discharge of nerve-force from the higher brain-centres. In health the restraining of all such excessive and meaningless discharge seems to be one very important function of the cortex. But even in health it is noticeable that this power of inhibition varies with the growth and development of the individual, being stronger at one time in the life of the same individual than at another, and even varying with the health and strength of the person. This subnormal inhibition is of common occurrence in so-called "nervous" people. Such persons are characterized by excess of muscular movement, quite often by extravagances of speech, though not sufficiently extreme to be called pathological. Finally, this power of healthy inhibition is modified greatly by hereditary influence.

The inhibitory and co ordinating power possessed by the higher nerve-centres in the brain is slight in infancy, and increases with age and development. The infinite random and meaningless movements of the infant's arms, legs, and facial muscles in response to external stimuli, are only so many outlets for nerve-force unchecked by inhibition and co-ordination. They constitute the physical expression of the infant, and illustrate perfectly its automatic and reflex character. Meynert says: "In consequence of irradiation and the lack of cortical inhibition upon the subcortical gray substance, we find in the child imperfect mimical expression; and in its stead we have pronounced spasmodic contractions, which, according to the spirit of the observer, are interpreted either as laughing or crying. The same is true of those afflicted with *dementia paralytica*" ("Psychiatry," Am. Trans., Appendix, p. 273). Defective inhibition, due to organic or functional disease of the cortex, is one of the chief factors of the morbid physical expression of the insane. Excessive and needless movements of the various muscles of the face and body may be due in the child to the imperfect development of the inhibitory centres, or in the adult to pathological conditions of these same centres; or among adults we may find those in whom healthy inhibitory power has never been developed, simply from lack of proper training in childhood.

III. *The trophic changes consequent upon the processes of waste and repair that are constantly occurring in the cerebral cells.* The entire question of cell waste and nutrition is imperfectly understood. There is no doubt that this branch of cerebral dynamics will receive constantly increasing attention from the physiologist and pathologist of the future. This process by which the cell stores up energy, which in some mysterious way it abstracts from the external world and then liberates through efferent tracts to the muscular system, is an admirable illustration of the law of "Convertibility of Forces." Not one of the forces of nature is lost; it is simply transformed and appears in some other form. But while the cell is engaged in this delicate process still another series of changes is taking place within its own structure, the process of waste and repair. No more delicate adjustment exists in the entire natural world than this equilibration that is maintained in the normal cerebral cell. The slightest disturbance in the protoplasm means impairment of function. This impairment of function, due to primary nutritional defect in the cell, may appear at the periphery as imperfect muscular tonicity, or in impaired nutrition of external parts, or in sluggish and irregular muscular movement. As Warner says, "It appears probable that a very distinct analogy may be made between series of movements and series of acts of growth, and that similar laws may govern both" ("Physical Expression," p. 81). Both "trophic action" and "kinetic action" are the expression of cell activity in the central nerve-mechanism.

Concerning the importance of the cerebral cell, Dr. Lewis says: "We may safely exalt the nerve-cell to a position of the very highest importance in our problems of mind. It is on this account highly important that the nerve-cell of the cerebral cortex should be the subject of careful study by all interested in psychological medicine, and that due attention should be paid to the conditioning of its functional activities, and to the results of its nutritional impairment, disease, and death.

"Suspended within a sac in direct connection with the lymph-channels surrounding the blood-vessels, or rather its own special nutrient capillary, the nerve-cell becomes liable to any influence, however trivial, disturbing the blood-stream in its neighborhood. A quickened circulation, a retarded flow, an anæmic state of the cortex must influence the functional activity of these centres of feeling and thought. A vitiated quality of the blood, or the presence of toxic agents introduced from without, or

elaborated within, the economy will affect them in a greater or less degree, while the activity of the lymph connective system in the removal of the effete products of functional wear and tear will play an all-important *rôle* in the same direction" ("Text-Book of Mental Diseases," p. 484. W. Bevan Lewis). Likewise Dr. Edward Cowles, in the Shattuck Lecture for 1891, bears excellent testimony to the train of symptoms following "weakness and toxic irritation of the central mechanism" ("Shattuck Lecture for 1891," p. 52). Thus it happens that nutritional changes hereditarily pre-established in the cerebral cell, or initiated therein by overwork and neglect of the laws of health, become reflected outward in the physical expression of the individual. Clinical illustration is abundant among the insane; but of this more hereafter.

Finally, it may be said that physical expression (and particularly that portion that is circumscribed by the facial region) is largely automatic, for the most part involuntary, and that it is developed in an entirely mechanical way. It belongs to the large class of reflex movements, and is one of the ways in which stimulations initiated within a central organ, or communicated to it from without, are reflected outward along certain nerve-tracts to terminal muscular attachments. The expression of the emotions, for instance, may be referred back to certain broad fundamental principles that obtain in the lowest radiata as well as in man. Physiologists are quite well agreed that the various emotions seek expression in muscular movements that are either defensive or sympathetic in character. Meynert says: "As movements of expression vary with the emotions, these movements must be either of an aggressive or repulsive character. We will find, with regard to the child in particular, that all physiognomic phenomena come under these two heads" (Meynert: "Psychiatry," Appendix). It is in obedience to this fundamental principle that the jelly-fish approaches toward and endeavors to enclose whatever is agreeable in the way of food, and contracts from and repels whatever is disagreeable in character. In like manner man, though in an infinitely more complex way, as might be inferred from his highly complicated and specialized nervous mechanism, draws near or touches whatever is pleasing, and shrinks from or repels whatever is displeasing. The principle in either case is the same, though in man the mechanism through which the feelings are expressed, as well as the feelings themselves, have become so complex that the original physiological principle is nearly lost sight of.

Individual expression, then, is a variable quantity, developing and changing with the growth of the person, and varying with his moods. In infancy physical expression is simple in character, is limited to innumerable reflex movements which, in the main, are sympathetic or defensive. At this age nerve-force is generated and liberated along different efferent routes, with little restraint. Soon after, or even during early infancy, inhibitory power is developed in the cortical centres, and nerve-force is conserved for future use. Undoubtedly, in earliest childhood muscular tonicity is established by the continuous normal discharge of nerve-force from the cerebral cortex over the shortest and easiest, and for that very reason, the most habitual routes to the muscular periphery. This tonic action of the cerebral cells, which gives to each countenance its characteristic expression, unquestionably receives a powerful influence through heredity. This transmission of the cerebral cell-structure to offspring explains the similar expressions so often seen in different members of the same family. Hereditary transmission plus the inhibitory influences that are developed by education, discipline, and the many attritions of civilized life, modify the tonic action of the cerebral cells upon the facial and other muscles, so that when adult life is reached an individual acquires that expression of maturity that is peculiar to him. It is difficult to define just what it is, and how this mature expression of the adult differs from a certain unfinished and undeveloped expression of childhood and early youth: there is, however, a vast difference in the facial expression of an individual in these two periods of his life, and there can be no doubt that the mature expression of adult life depends upon, or corresponds to, a modification of the cell-structure of the cerebrum. Even in early infancy a wonderful change is noticed in the facial expression during the first few weeks and months of infancy, illustrate perfectly the outward nerve-muscular manifestations which correspond to an inner development. Muscular movements, at first only fleeting, by constant repetition become habitual and permanent. In this mechanical way will heredity, the social, intellectual, and moral life of the individual mould the physiognomy.

An explanation is here found for those singular reversions in old age to certain family expressions which have characterized parents, uncles, aunts, or grandparents. Conolly thus refers to this interesting fact: "On the other hand, persons of ardent dispositions, who have worn all through their active years the physiognomy of an excitable mind, sometimes lose by degrees all this muscular agitation, and as they descend into the calm twilight of age, revert in appearance to that of parents or uncles or aunts still remembered by friends of the family. After death the face often exhibits these resemblances; and, above all, the placidity which human events can disturb no more. When there are exceptions to this, and the countenance bears in the latest years of life the stamp of mean or angry sentiments, which sometimes indeed shock our observation even in the coffin, the effect seems to be a result of the habitual impress of such feelings on the muscular part of the physiognomy during the greater part of life, with few or no benign alternations" ("The Physiognomy of Insanity," by John Conolly, M.D., *Med. Times and Gazette*, May 15, 1858, page 498).

Quite striking and interesting is the change that is sometimes witnessed in the faces of the chronic insane after death. In the faces of these cases there seems to be a partial reversion toward former and more natural expression at the time when death puts an end to the diseased action of the brain cells. Such cases will, after life is extinct, look more natural and more like their former selves, so their old friends say, than they have appeared for years. It would seem that in these cases a strong individual expression had been attained through the influences of heredity and early training, which had been modified for many years by the perverted motor action due to slight pathological changes of the brain, but which expression had returned immediately upon the cessation of the diseased action of the cerebral centres. On two or three occasions within my own experience, when I felt regret for the sad change of countenance that the friends must see in the face of some patient about to die, and who, for years, had been afflicted with chronic alienation, I have been singularly surprised to see how much better the face appeared after death. Certain lines of expression, and a peculiarly unpleasant cast of countenance that I had been accustomed to see for years, and to regard as habitual, had entirely vanished with the cessation of life, and a completely different and, to me, new expression (but which the friends recognized as characteristic of a condition of mental health in bygone years), had taken its place. This singular phenomenon was noticed by Dickens in "Little Dorrit." The Father of the Marshalsea says: "Unless my face when I am dead subsides into the long-departed look, they say such things happen, I don't know, my children will never have seen me."

The study of the physical expression of the insane enables one to observe the mechanism of expression from a pathological stand-point, and yields still further confirmatory evidence of the reflex and involuntary character of expression in general.

III. The Physical Expression of Insanity.

Knowledge of the mechanism of facial expression in health suggests the inference that the physiognomy must be variously modified by disease. If individual expression be due to a close functional relationship between

activity of the cell-structure of the encephalon and muscular movement at the periphery, it is evident that diseased conditions of the central nervous system must in some way exert an influence upon the physiognomy.

Gowers, following in the line of Hughlings Jackson's investigation, to the effect "that the whole brain is made up of structures which subserve sensory-motor processes, and that into such processes all its functions may be resolved," adds, "but that every structure of the brain concerned with sensation proper is connected, directly or indirectly, with a part concerned with motion, may be regarded as a proposition scarcely needing proof." According to this theory the motor disturbances in epilepsy are due to morbid functional conditions in the convolutions, thus demonstrating a most intimate relationship between peripheral muscular movement and diseased cell-activity in the cortex.

In epilepsy an illustration is presented of great motor disturbance and marked alteration of the physiognomy, due to some powerful temporary interruption of healthy cell action in the convolutions. In insanity, and many other allied morbid states, additional opportunity is afforded for observing still further physiognomical alterations due to morbid, though more persistent, changes in the nerve-centres of the convolutions.

Indeed, it is interesting to note, in this connection, the remarkable influence that habitual mental and moral conditions exert upon the physiognomy. Certain types of character are apt to be associated with a certain configuration of countenance. So universally has this been observed, and so frequently have certain mental and moral traits been associated with peculiar facial expressions, that artists and dramatic actors have represented their characters with this or that cast of countenance according to the character of the individual they wish to portray. We often say of the person whom we may pass on the crowded street of a city that he has an ugly face, and we feel quite confident that he may be a man of low, brutal instincts; or, meeting another person, we say of him that his countenance is that of a noble, high-minded individual. Note the faces of the convict class in our prisons and penitentiaries; they are nearly all of them unpleasant to look upon, and many are positively repulsive. The photographs of noted criminals present few features that are attractive.

The physiological reason for this individuality of expression undoubtedly lies in the fact that the expressions oftenest repeated in the face are those most likely to remain, and in time these become the predominant expressions which individualize the countenance. Hence the criminal, in quite a mechanical and involuntary way, establishes what we recognize as a criminal countenance; men of high moral sentiments, and noble, generous impulses, acquire a certain permanent facial expression associated with these more ennobling sentiments. Undoubtedly, specific cell changes within the cerebral centres correspond to these variations in personal character, and have their indices in the face.

In this connection it is interesting to notice the methods of great dramatic readers and actors. These attain their marvellous perfection in the portrayal of their assumed characters, not by studying their attitudes and facial expression before a mirror, but by a process of intense abstraction they lose themselves and become identified with the assumed character to the degree which produces in their appropriate brain-centres conditions identical with those which are real in the characters they represent. The difference is this: in the one the expression is the reflex of real character, while in the other imagination and the power of abstraction throw the brain-centres, for the time being, into the same physiological state which, through muscular channels, is reflected in the countenance and attitudes.

Few possess this great gift, and the difference between the common actor and the great histrionic masters is that the former are usually mere mechanical imitators, while the latter absorb, in the way described, the character they seek to portray, and, for the time being, think, breathe, act, and live in the assumed part. Who that has seen Salvini impersonate Othello has not felt, at moments in the progress of the play, that it was the real Othello whom he saw and heard speak, and not Salvini? And in the wondrous play of his features how plainly could the English auditor read the thoughts and feelings of the Moor, and interpret the words of the great tragedian, though unfamiliar with the language in which they were spoken.

The association of a lower grade of physical health with permanent and fixed criminal tendencies is not always imaginary. Many habitual criminals have been born of unhealthy or intemperate parents, and have spent the formative and growing part of their lives amid hygienic surroundings and conditions that were well calculated to stunt all healthy physical development. Stevenson, in the most interesting psychological study, Dr. Jekyll and Mr. Hyde, recognized this association of evil qualities with defective physical organization, and a healthier and more robust constitution with a more noble and generous character. Hyde was stunted, dwarfish, and anæmic; Jekyll larger, well proportioned, and ruddy. The impression which Hyde left upon the lawyer's mind is not an unusual occurrence. "The lawyer stood a while when Mr. Hyde had left him, the picture of disquietude. Then he began slowly to mount the street, pausing every step or two and putting his hand to his brow like a man in mental perplexity. The problem he was thus debating as he walked was one of a class that is rarely solved. Mr. Hyde was pale and dwarfish, he gave an impression of deformity without any namable malformation, he had a displeasing smile, he had borne himself to the lawyer with a sort of murderous mixture of timidity and boldness, and he spoke with a husky, whispering, and somewhat broken voice. All these were points against him, but not all of these together could explain the hitherto unknown disgust, loathing, and fear with which Mr. Utterson regarded him. 'There must be something else,' said the perplexed gentleman. 'There is something more if I could find a name for it. God bless me, the man seems hardly human! Something troglodytic, shall we say? or can it be the old story of Dr. Fell; or is it the mere radiance of a foul soul that thus transpires through and transfigures its clay continent?'"

These various types of countenance have a new interest to the psychologist when he considers them from a physiological point of view. The defective, ill-nurtured brain may not lead the individual into insanity, but may, even in spite of proper early training, develop a criminal tendency and character. In either case, however, the cortex by its intimate connection with the motor centres below it, and through them with the muscular periphery, is quite certain to modify in some way the muscular play of the countenance. We need not wonder, then, at the hardened, coarse features of the criminal, for during his whole lifetime the higher centres in the brain have received but little active development, his entire life has been animal and sensuous; and in the absence of any exercise of the higher mental faculties there have never been implanted in his countenance those more refined and elevated expressions that are the outgrowth of the moral and intellectual life.

Incapable of anatomical demonstration as this may seem to be, there can be but little doubt that the higher mental faculties do seek expression through activity of the cortical centres; and inasmuch as we know that diseased conditions of these cortical centres do very materially modify facial expression, the inference is reasonable that the unpleasant facial expression of criminals has a physiological foundation in certain structural conditions within the cerebrum.

The illustrated volume by Inspector Thomas Byrnes, of New York, entitled "Professional Criminals of America," is quite interesting to the physiognomist. With few exceptions, the portraits represent men of hardened character, and their countenances give strong evidence of entire lack of sympathy with whatever is ennobling and elevating in life. The expression of their eyes is either furtive and treacherous, or suspicious, or else bold

and brazen. Their mouth and lower jaw bespeak the grasping, selfish, animal life they lead. As might be expected, the faces of women malefactors give evidence of the most striking degeneration; there is little left in their bold, coarse features to remind one of the gentler, more sympathetic qualities of their sex.

It is interesting to note how facial expression, among criminals even, is modified by the degree of intelligence of the individual. The shrewd, well-informed, ingenious bank burglar, possesses a very different face from the low-lived, more ignorant river thief. As Inspector Byrnes says, the latter "are as hard-looking brutes as can be found;" while the former may not only be modest and gentlemanly in appearance, but even people of considerable education. It is quite evident that these latter are the exception, and that they owe their finer countenance to their intelligence and intellectual ability, as well as to a certain moral development; for it must be borne in mind that many of these professional burglars live dual lives. Men of this class often have homes and children whom they are educating in good schools. The ties of affection exist as strongly in them as among men of correct life. It is not difficult in their cases, therefore, to account for an improvement in the type of the criminal countenance.

Occasionally there appears one of those strange moral monstrosities in whom much shrewdness and even intellectual ability is associated with an entire absence of conscience. Such individuals, while keeping up a show of moral and social respectability, may all the while be entertaining the most criminal plans. As a rule, the facial expression of such persons is unpleasant, and their features reveal the more purely sensuous life they are living, as well as the character of the impulses which direct their daily thoughts and actions. These unfortunate beings usually manifest a persistent tendency to develop a morbid passion for cruelty or crime of some sort, and this in spite of any careful early training in the right direction which they may have received.

To this class belong such cases as that of William B——, reported by Dr. Clarke in the *Journal of Insanity* for July 1886; and by Dr. Hack Tuke, in the *Journal of Mental Science* for October, 1885.

E. H. Rulloff, executed at Binghamton, N. Y., and whose case was reported in the *Journal of Insanity* for April, 1872, is another illustration of this same class. He possessed certain remarkable intellectual accomplishments, but seemed entirely devoid of any moral sensibility. Unfortunately no photograph of his face during life could be obtained, while those taken of the plaster-cast made after his death are deficient in details. Dr. Burr, of Binghamton, in a paper, on Rulloff, read before the Medico-Legal Society, September 14, 1871, makes some remarks upon this notorious criminal's general appearance which are so pertinent to the subject under discussion that, in lieu of a photograph, I cannot forbear quoting them. He says: "His countenance when in repose was stolid and indifferent; when giving vent to his frequent ebullitions of passion, it was repulsive and forbidding; but when animated by some subject in which he took an interest, like his favorite theme, philology, his features assumed a lively, active, and intelligent expression. In walking he stooped forward, and had a shambling, shuffling gait, such as he would be very likely to acquire during his long confinement in the various prisons in which he had been incarcerated.

"His entire organization, as has been remarked of the cranium, was coarse. It was not without vigor or powers of endurance, but its material was not of the best quality, and was wanting in the fine finish which is now regarded as the best development of the human structure. In some respects his organization resembled that deteriorated condition, or that low type of physique, which has been declared by Mr. Bruce Thompson, to be characteristic of criminals as a class."

The human countenance, therefore, possesses a singular interest for the physician, because in its manifold expression he may read the reflected impress of certain physiological and pathological changes taking place within the cerebral centres. In forming a diagnosis nearly every physician is influenced in large measure, though often in a tacit and almost unconscious manner, by the facial expression of the individual whose case he may have under consideration. The wise and observing general practitioner often makes a correct diagnosis upon first entering the sick-chamber; he takes in at a glance the peculiar *facies* of his patient and sees in it the pathognomonic signs of some disease. The dusky countenance, the sunken cheek, the dilated nostril, the short and almost panting breath, indicate phthisis even before physical examination. The injected eye, the trembling tongue and fingers, the hurried frightened glance over the shoulder, the sudden start and involuntary repelling motion of the hand, with the intent look of fear peering into corners and toward the direction from which any novel sound may proceed, suggest the delirium of alcoholism. And so the psychiatrist is influenced at times, almost more strongly than he can describe, by certain glances of the eye and a certain configuration of the countenance, and is led to infer alienation, although it would be extremely difficult for him to satisfactorily convey this evidence, so convincing to himself, to another person, or to make it satisfactory to a jury. Nevertheless, it is important evidence to him, and in the absence of incoherence, or of any apparent delusion, he is induced to believe that his patient is mentally unsound, and so persist in his examination or demand repeated examinations until he has struck the key-note of his mental weakness. And how frequently is the reverse true! The examining physician feels sure that the individual before him is not insane; the eye, the countenance in its entirety, indicate to him more definitely than he can formulate the same in language, the repose and the equipoise of health.

The words of Dr. Luther V. Bell, written some twenty-five years ago, in a deposition concerning an insane woman, are interesting and quite pertinent to the present subject. He says: "The reasons which convinced me that Mrs. ——— was laboring under a grade of confirmed insanity of long standing, of probable incurability, and to an extent depriving her of responsibility for her actions, may be included under two divisions. The first may be called personal convictions, not capable of being fully conveyed to another mind, such as the expression of countenance, of eye, of manner, of habit of receiving and communicating thought, which a long acquaintance and domiciliation with the mentally diseased compelled me to accept as the truth; outer proofs of an inner morbid condition, yet which can hardly be so depicted or explained to the inexperienced. All profound and grave maladies have their specific physiognomy, more or less clear and capable of being described; some awfully clear and pathognomonic, like the odor of cancer, or the face of advanced phthisis. Insanity has its own delicate characteristics of face, eye, manner, reasoning, feeling, which can be read by the expert, but which would not be appreciable to the merely casual observer. His power in this regard is not capable of being transferred to another mind, but must die with its possessor."

It is just here that instantaneous photography assists the psychiatrist and enables him to transfer to another or to retain for future reference, through the sense of sight, all those delicate characteristics of face, eye, manner, and the like which are caught by the camera and retained on the sensitive plate—a thing that was not practicable at the time Dr. Bell gave his deposition.

In the present essay it is proposed to analyze the physiognomy of different insane persons. As one result of such analysis we shall find that the facial expression of the insane is determined by one or more of several pathological conditions. By studying these conditions separately we gain a clearer view of the significance of physical expression in insanity, and thus confirm the views already expressed concerning the physiology of physical expression.

These pathological conditions may be considered under three heads:

I. The trophic or nutritive disturbances which accompany the disease.

II. Impairment of healthy inhibition which is so frequently associated with insanity, and one result of which is weakening of the faculty of attention.

III. Excessive or defective nerve-muscular activity of an involuntary character, dependent upon morbid irritation or degeneration of the cerebral structure.

To these may be added the different positions and expressions of the eye, which, though possibly dependent upon the foregoing pathological conditions, are still of such significance as to deserve separate mention.

In connection with the third condition, that of varying motor disturbances, a study of various attitudes of the insane, as well as the different positions of the hands and the manner of carrying the head and the entire body, will be found both suggestive and interesting, as affording striking confirmation of the physiological principles previously discussed.

I. *Modifications of the Countenance in Insanity which are Due to the Trophic or Nutritive Disturbance Attendant Upon the Disease.*—In a large majority of cases insanity is itself caused by depreciated physical health. Dr. C. F. Folsom says: "The exhaustion and the disturbed cerebral circulation arising from acute and chronic diseases, profound anæmia, or prolonged mental strain, associated with emotional disturbance from any cause, are among the antecedents of insanity" ("Mental Diseases," p. 117). The association of neurotic and unhealthy physical conditions in different members of the same family is quite common. Of most frequent occurrence is the association, among different individuals of one family, or an alternation in the same person, of phthisis and insanity.

Aside from such causes as hereditary transmission, alcoholic and venereal excesses, traumatism, and with the exception of its occasional appearance as one of the sequelæ of some other disease such as epilepsy or some of the acute infectious diseases as measles, scarlet fever, and the like, insanity in the large majority of cases is caused by depreciated physical health with or without the association of some moral disturbance. The most frequent history given the physician is the following sequence: Overwork, loss of sleep, loss of appetite, indigestion, emaciation, increased worriment of mind, and, finally, actual insanity. The insanity appears as the result of the imperfect nutrition of the brain, which was in its turn produced by disordered health caused by improper attention to rest and digestion.

On the other hand, insanity itself may act as a cause of the deterioration of physical health. Oftentimes it aggravates the profound physical depression which was, in the first instance, the primary cause of the mental disturbance. We readily understand the reason for this secondary action of the brain upon the general health when we consider that this delicate organ presides over the entire nervous system, and that any disturbance in its action is sure to modify the healthy distribution of nervous force in the different parts of the body. Repeated and long-continued congestions of the delicate centres in the cerebral cortex, attendant on nearly all attacks of acute insanity as well as in the exacerbations occurring among the more chronic forms of the disease, lead to imperfect restoration of cell-structure in this organ, or to an unhealthy hyperplasia of the delicate tissues. Such changes in the brain result in its imperfect nutrition. Impaired nutrition of the brain leads to defective bodily health in various ways: either the morbid ideas which are the result of the brain disturbance lead to refusal of food, or the supply of healthy nervous energy to the entire alimentary canal is so interfered with that all the processes of digestion are improperly performed and healthy assimilation is impossible, or the activity of the cells in the cortex may so interfere with normal vaso-motor innervation that the natural circulation of the blood in other parts of the body is disturbed. In either case a depreciated state of bodily health, a decidedly lowered vitality, with diminished resistance, is the result.

This depreciated state of the general health is manifested in the condition of the skin, the hair, and mucous membranes. Every physician who attends upon the insane is familiar with the cold, clammy hands so characteristic of this class of patients; or with the dry, scaly state of the epidermis; the brittle, dry hair; the furred tongue and oftentimes offensive breath; the peculiar flabby condition of the skin of the face, with its pasty, lustreless color. All these characteristics, though not always present, still prevail in the majority of cases, and indicate that the general health has been impaired either by the cerebral disturbance itself, or by the constitutional causes leading to the brain trouble.

Although the photograph cannot preserve all the conditions of ill health above referred to, still the flabby countenance with its lack of healthy tonicity; the "lean and hungry look," and many of the signs of impaired vitality, are well retained and form a striking feature of any collection of portraits of the insane.

In a general way the study of the countenances of the insane leads to the conclusion that nearly all acute, recent, and very active insanity is attended with emaciation, sometimes only slight in degree, at other times quite extreme. This is quite noticeable in acute mania, acute melancholia, in the depressed stage of *folie circulaire*, during the active excitement of paresis, in acute primary dementia, or in dementia secondary to acute or chronic insanity, especially where the progress of the disease has been rapid.

Those forms of insanity in which there is an excessive elimination of nerve-force from the cerebral centres, are always attended by emaciation. In acute mania, some forms of acute melancholia, the maniacal stage of paresis, this constant and extreme elimination of nervous energy is manifested in almost incessant motor activity, and in these cases we always notice emaciation and general physical prostration.

Case XLII (see p. 519), acute mania, illustrates the emaciation attendant upon constant motor excitement in Fig. 337, A; while in Fig. 338, B, the return to health is evidenced as much by change in nutrition as by intelligence of expression.

In other cases the nervous system may be profoundly affected, and, though motor activity is not a symptom, still the trophic disturbances are as pronounced as in those to which we have just referred. In these cases the motor and the ideational centres seem to be overcome by the force and suddenness of the nervous shock, and there ensues an entire absence of activity in these same centres. There is no longer an elimination of healthy nervous energy from the cerebral region, and hence there is not only a cessation of normal functional activity of all the bodily organs such as the stomach, intestines, liver, kidneys, heart, and lungs, but there is also a paralysis of the centres in the cortex. As a result the patient is not only utterly exhausted and physically prostrated, but he is also mentally confused and dazed. An illustration of this condition, with its attendant trophic disturbance, is seen in Case XXXI., A and B (Figs. 313 and 314). This patient came into the asylum in a state of complete mental stupor; she would neither eat nor speak, gave no heed to personal cleanliness, but would void her urine and fæces wherever she might happen to be, whether standing up or lying in bed. She would stand for hours in the attitude seen in A, her eyes fixed and motionless, and no amount of urging could excite her attention. She became exceedingly emaciated, although she was fed daily upon the most nutritious diet. Comparison of pictures A and B with C (Fig. 315), taken at time of discharge and recovery, illustrates the wonderful nutritive disturbances that occurred during her sickness. Undoubtedly, the profound trophic alterations in her case were due primarily to the extent and severity of the diseased action in the cortical centres.

Another fact is worthy of notice.

Whenever a patient, suffering with some form of insanity, after a long period of mental disturbance, begins to regain flesh and weight without making any corresponding mental improvement, we have reason to fear

that the alienation in this patient may become chronic. In such cases it is not at all improbable that the cerebral structure has accommodated itself to the morbid processes which have been disturbing it for so long a time. The cells in the cortical region continue to act in

FIG. 313.—Case XXXI. Melancholia with Stupor. A, showing full-length attitude maintained for hours. Ocular divergence, self-absorption, and emaciation. (From photograph taken by author.)

their newly acquired morbid manner, while those parts which more particularly preside over the functions of nutrition and assimilation and of organic life act automatically and as naturally as ever. Thus, though the individual may have all the symptoms of chronic delu-

FIG. 314.—Case XXXI. B, showing nearer view of head. (From photograph taken by author.)

sional insanity, or of mental weakness in some form, still the processes of nutrition and assimilation are normally performed, and he may attain a good degree of physical though not of mental health.

More frequently, however, increase of flesh and perfect physical health are coincident with mental convalescence and recovery. In nearly all cases of chronic insanity there is that condition of lowered vitality which is generally the inevitable accompaniment of the disease. The flabby skin, lustreless eye, general absence of healthy plumpness, and the drooping head, all indicate deficiency of normal nutrition. All these symptoms are more manifest in the persons themselves than in their photographs; yet the latter plainly signify the trophic disturbances associated with the disease.

Melancholia is almost invariably attended by pronounced trophic disturbances, and photographs of this class always show what marked inroads upon physical health this especial form of mental disease may make. In no case is this more noticeable than in XXXIII. (see page 528). The emaciation was extreme. Every mental faculty seemed paralyzed, and many bodily functions, such as digestion, assimilation, and nutrition appeared to be almost entirely suspended. His gradual return to mental health is marked by corresponding improvement in nutrition, and shows quite plainly in Figs. 346, 347, and 348.

This depreciation of physical health during the height of the attack, its return and perfect establishment at time

FIG. 315.—Case XXXI. C, same person after recovery. (From photograph taken by author.)

of mental recovery, is quite noticeable in the portraits of Case XXXI., A, B, and C. In Case XLII., Fig. 338, B, taken at time of recovery, when compared with A (Fig. 337), presents very marked changes in physical health.

Alternations in loss and increase of flesh are often noticeable in cases of insanity. During the active stage of paresis, when there is very marked cerebral activity, attended with pyrexia and great motor disturbance, there is much tissue waste, and the patient becomes quite emaciated. When the excitement abates, the fever disappears, and motor activity ceases, then the appetite is apt to increase to an excessive degree, assimilation goes on as usual, and the patient sinks into a passive, quiescent state in which flesh is accumulated to an almost unnatural degree. In cases of folie circulaire there is often increase of flesh and strength during the active stage, and during the period of depression there is marked emaciation. All the processes of assimilation seem to be in sympathy with the depression of mind, and when the reaction comes increased appetite and improved assimilation, together with increase of flesh and strength, also reappear.

In other cases, although there is no real improvement in the mind, still a change in the character of the delusions leads to a more hearty ingestion and assimilation, and the patient's physical health improves, although mentally he may still be far from well.

In many of the chronic forms of insanity, where there

is little undue motor activity, and especially in that form known as paranoia, the bodily functions are carried on quite naturally. In a well-regulated hospital there is so little to disturb the lives of these patients, their hours of eating, sleeping, and bathing are so regular, that even though their cerebral condition is in no way improved, their physical health is quite good, and oftentimes the accumulation of flesh in these cases is almost pathological. A removal of such patients to a less favorable situation often results in a rapid deterioration of their physical health, or at least in a loss of their flesh. In all cases of chronic insanity, however, marked improvement in physical health is more apparent than real. There is, as we have seen, an occasional accumulation of adipose tissue; but in such cases there is often a deficiency in that general vitality and energy which we associate with health, and which is so effective in resisting disease.

To briefly recapitulate what has been said concerning the trophic and nutritive modifications of the physiognomy in insanity:

1. In the majority of cases there is impaired general nutrition due either to (*a*) congenital brain deficiency; (*b*) to abnormal or excessive elimination of nervous energy from the brain, thereby weakening and interfering with the functional activity of that organ; or (*c*) to permanent brain weakness acquired as a result of chronic insanity. In these three ways the functional activity of the brain as a distributor of nervous energy to the organs of digestion and assimilation is interfered with, and the general health suffers as a result.

2. Occasional alternations of flesh and emaciation, of improved and impaired physical health in the same individual, and due to fluctuations in the functional activity of the brain.

3. Occasional coexistence of physical health and mental disease—a condition of things which is oftener apparent than real, and dependent largely upon the fortunate environment of the patient.

II. *Modifications in the Physical Expression of the Insane, Due to Impaired Inhibition.*—The inhibitory power is recognized as playing a most important part in the intellectual and physical life of man. Whether inhibition is a purely metaphysical attribute of mind, or a special function having its seat in specific centres of the brain, its importance as a factor in the life of the individual cannot be doubted. Many writers have denied the existence of special inhibitory centres. Many physiological and psychological facts confirm their views.

G. H. Lewes argues with much force against the existence of special centres of inhibition. He attempts to explain the phenomena of inhibition by what he calls the Law of Arrest. "The Law of Arrest is only another aspect of the Law of Discharge, and may be regarded as the conflict of excitations." According to this theory, each nerve tract and centre possesses inherent inhibitory properties of its own. The strongest excitations prevail: "The discharge is only the resultant of the conflict along the line of least resistance; the arrest is the effect of the conflict along the line of greatest resistance" (G. H. Lewes, "Physical Basis of Mind").

Meynert advances the theory that the gray matter of the brain and cord presents a certain resistance to nerve-conduction. Increased irradiation of any irritation is accompanied by increased resistance in nerve-conduction. "It is evident then," he says, "that inhibition resulting from resistances introduced in nerve-tracts accompanies the simplest reflex processes."

Many physiological and pathological data lead us to infer that nerve-tissue, and particularly the gray matter, possesses certain inherent tendencies to resistance to nerve-conduction. Herein man widely differs from the lower animals. For in them, this resistance to nerve-conduction, which we recognize in man as a part of his inhibitory faculty, is incapable of development, but remains stationary through life just as it was transmitted at birth by heredity. In man, on the contrary, this property of resistance may be developed by individual training and experience. Hence the inhibitory power varies with the person: there is no universal inhibitory standard that can be applied to all alike.

The possession of a high degree of inhibition is often due to an active exercise of the will-power; hence, perfect inhibitory capacity is usually associated in the same individual with a strong and active manifestation of the will. Carpenter says: "Now the man in full possession of his volitional power can use it, (1) in giving bodily effect to his mental decision, by either putting in action the muscles which will execute the movements he has determined on, or by restraining them from the action to which they are prompted by some other impulse; and (2) in controlling and directing that succession of mental operations by which the determination is arrived at" (Carpenter, "Mental Physiology," p. 378).

In the gradual evolution of the inhibitory power the will plays a most prominent part. By active and constant exercise of the will an individual may develop marked inhibitory power. Inhibition represents gradual growth, therefore, and varies at different periods in the life of the same individual. At birth, and during early infancy, it scarcely exists. Every act that the infant performs is the impulsive and spasmodic result of sensory stimulation. During childhood the inhibitory power receives its first training and development. The child learns to govern himself. Experience and his parents teach him that the mere impulsive gratification of every whim that may arise, of every appetite that suggests itself, is not only not desirable, but may be fraught with disastrous results, both here and hereafter. In youth and manhood this power of inhibition receives constant education. The experiences of life all tend to develop it, if the will insists upon it.

In the cultivation of man's moral nature the successful development of inhibition receives a good illustration. Man's unbridled animal instincts might lead him into habits of vicious and selfish indulgence, of which the criminal records present abundant illustrations. The teachings, however, of religion, morality, and even the instinct of self-preservation, lead him to place a check upon these mere animal indulgences. At first the conflict may be difficult, as the history not only of individuals but even of entire nations, will testify. Individual persistence succeeds, however, in implanting in the person such power for resistance that these temptations not only cease to have any allurement, but even become loathsome. Such inhibitory resistance is transmitted by heredity.

The inhibitory power, therefore, may vary greatly among races of men as well as among individuals. Education is certainly a prominent factor in its development. Civilized man possesses the inhibitory power to a greater degree than the savage; the educated, in this as in many other respects, are vastly superior to the ignorant. Indeed, success in life may be measured by the degree of healthy inhibition possessed by the individual.

Climatic and hereditary conditions exert a powerful influence in modifying and developing the inhibitory power. And thus we can understand why it is that the people of one nationality and climate differ so materially from those of another in the possession of this faculty.

We may briefly summarize by saying that inhibition seems to be a restraining power which is implanted in the mind, and incorporated as it were in the nervous system of the individual. It is largely a matter of individual growth, and depends for its successful development upon the strong and healthy exercise of the will. There is also evidence that the inhibitory power is modified in various ways by climatic and hereditary influence. It is also evident that, when once this inhibitory and restraining power is implanted within the nervous organization of an individual, its habitual and almost involuntary exercise is elicited by the presentation of the proper stimulus. Thus habits and tendencies which have only been repressed with the greatest difficulty and after the most active exercise of the will, receive frequent and comparatively easy restraint when once a tendency to their inhibition has been fairly established by the individual.

The inhibitory power seems to be intimately associated

with all our higher faculties, and in common with them seeks expression through functional activity of the cerebral cortex. The inference is natural that functional or organic disturbance of this region should be attended by disordered inhibition. Among the earliest manifestations in insanity is impairment of the inhibitory power.

In health the inhibitory function is exercised in a twofold manner: First, in checking irrelevant trains of thought, repressing whatever is impertinent to the subject engaging the attention; and secondly, in checking certain muscular movements which, though they naturally follow the stimulations which have preceded them, still, for the time being and with other objects in view, are undesirable and out of place.

It is not surprising that the inhibitory function, so intimately associated with all the higher activities of the mind, and probably identified with cell-activity in the cerebral cortex, should be among the first to become disordered in insanity. A careful analysis of the symptoms that arise during the premonitory and early stages of mental alienation discloses evidences of weakened inhibition.

Among the higher faculties the attention holds a most prominent position. Active exercise of the inhibitory power is indispensable to a complete awakening of the attention. And the success attained by any individual in the various walks of life may be measured by his power of inhibiting whatever is irrelevant, that is, by his ability to concentrate his attention upon the work before him.

Obersteiner has well said: "We can will that a certain action to which there exists a powerful stimulus should be repressed and carry out another. By inhibition of the former we concentrate our attention on the latter. . . .

"Ideas tend to call up other ideas by association, and naturally along the most easy channels. But we can check the current of ideation along the easiest paths and divert it into paths which are more difficult. We think attentively and inhibit continuously. The more powerful this inhibitory working of the attention, the more intense the thought, the more numerous the paths opened up, and the more productive in its consequences. It appears therefore from these considerations, that in every mental act, whether it be in the domain of sensation, volition, or intellect, there is seen an inhibitory power essentially the same in all cases" ("Experimental Researches on Attention," by H. Obersteiner, in *Brain* for January, 1879).

In the early development of insanity one of the first symptoms to attract the notice of the friends, and to arouse their suspicions of mental disturbance, is a manifest inability on the part of the patient to concentrate his attention. This will declare itself in various ways. The patient becomes inaccurate. If a mechanic he either accomplishes less work or is careless; if in business he makes frequent mistakes and fails to fulfil important obligations. All this inaccuracy and omission of detail is due to varying degrees of self-abstraction. The patient has lost the power of successfully inhibiting the fleeting thoughts or suspicions which crowd his mind and which supplant the ideas that immediately concern his daily work and life.

In health the individual possesses the power to turn his thoughts in the direction of his work or whatever may interest him at the time. Irrelevant ideas and sensations can be inhibited, and only those regarded which will assist the work in hand. But in the earlier stages of insanity, and in the more firmly established conditions of the disease, every morbid idea, and often every communication to the sensorium through the avenues of the special senses, acts as a diversion. The patient's power of attention is so easily distracted, he places such a morbid construction upon every new sight or sound, and his inhibitory power is so weak that healthy concentration upon affairs of real importance is an actual impossibility.

The asylum workshop affords an excellent illustration. Here you may study inhibitory incapacity in every stage of development. A stranger enters the room and probably half of the patients will cease working, some will arise from their seats, and possibly one or more will walk about the new-comer, looking him over inquisitively and either talking to themselves or to the visitor. And in what a scattered and desultory way is much of the work performed! Evidently ideas irrelevant to the occupation in hand absorb and divert the attention of these diseased minds into other channels. In just the proportion that the individual possesses inhibitory capacity, to just that extent does he seem capable of performing successful and intelligent work.

Bearing in mind, then, that weakening of healthy inhibition is one of the first results of insanity, we find this impairment of the inhibitory capacity manifested in the physical, and particularly the facial, expression of the insane in two ways:

1. There is inability to control the movements of the facial muscles. The insane make few attempts at concealing the facial expression of their feelings. With them impaired inhibitory power interferes with that slight volitional control which we possess over those facial movements that habitually follow certain emotions. In the familiar language of daily life the insane *look* very much as they *feel*, and their attempts at concealing their real emotions are few and unsuccessful.

2. For the same reason there is impaired inhibition, there is inability to concentrate the attention, the result of which is an expression of self-absorption quite peculiar and characteristic of the disease.

These two elements in the facial expression of the insane merit more discussion in detail. First, as to inability to control the well-known facial expressions of certain emotions. We must remember that the muscular movements producing facial expression are essentially reflex, and largely involuntary. When displeased we do not will our facial muscles to assume certain positions characteristic of displeasure; neither when amused do we will that they should contract in the way peculiar to the expression of amusement. As has been previously stated, the muscles, without any seemingly volitional effort of our own, assume these positions themselves in obedience to the special force transmitted to them from the cerebral cells along the intermediate conducting nerve-fibres.

Although the ordinary muscular movements concerned in facial expression are involuntary, still man does possess a limited control over them. This inhibitory influence over muscular contractions that are commonly reflex and involuntary is developed by education and experience; and is often carried to a high degree of perfection by persistent self-training in this particular direction. The emotions are more unreservedly expressed in the face of the child than in that of the adult; the ignorant and uneducated betray their feelings in their facial expression more frequently than do the intelligent; indeed, this power of controlling the expression of one's innermost sentiments may be the evidence of a healthy and well-balanced mind. This attempt at concealing these deeper feelings is practised to a certain extent and with varying success by every one. Sometimes a sentiment of pride, again criminal reasons influence an individual to inhibit the ordinary movements of facial expression. Thus a man may be bowed down with grief, and yet when he appears in public will, from a secret feeling of pride that leads him to avoid betraying his emotions to others, conceal every expression of sorrow. He will smooth out the wrinkles of pain on his forehead and appear calm and unmoved until by himself again. Or the criminal, who harbors motives of hatred and revenge, or who has committed some great crime, will conceal, or at least attempt to conceal, the malignant and guilty expression which would otherwise betray him.

To a certain extent, therefore, the normal involuntary and reflex movements of facial expression are inhibited in health. In insanity, however, the inhibitory power is so weakened by the disease that successful control of these movements is difficult.

The insane patient makes few and ineffectual attempts at disguising the feelings which oppress him. The conflicting emotions by which he is disturbed are reflected through the various motor-tracts to the face, and as a result we may often read the character of the delusions which preoccupy the mind. Thus the expression of the

countenance in acute melancholia is generally quite characteristic of a depressed state of the feelings; and what is especially noteworthy is the fact that this diseased expression is far more intense than would be the expression of similar emotions in the same individual in health. Impaired inhibition does not exercise any restraining influence upon the countenance, and, whether alone or in the presence of others, the melancholic presents the furrowed brow, the anxious and distressed expression about the eyes and mouth that are characteristic of these especial emotions, whether they proceed from natural or morbid causes. The only difference is that the normal manifestation of grief is modified by healthy inhibition, while morbid sorrow is persistent, intense, and not subject to outward restraint.

Indeed, the most marked illustrations of impaired inhibition are found among the faces of the melancholic insane. There is oftentimes in these cases a complete abandonment to the predominant emotion—the patient making no effort whatever to control the expression of the feelings. Darwin's remarks upon the facial expression of sorrow are particularly interesting, and, undoubtedly, are physiologically correct. As his explanation of the physical expression of grief is corroborated by the physiognomy of melancholia we will briefly refer to what he says upon the subject.

The muscles which are brought into play during the expression of painful emotions are the corrugators, orbicularis, pyramidalis of the nose, and the frontalis. These are what Darwin has called the "grief muscles" when they are placed in "conjoint yet opposed action," which action he thus describes: "When a person elevates his eyebrows by the contraction of the whole frontal muscle, transverse wrinkles extend across the whole breadth of the forehead; but in the present case (expression of grief) the middle fasciæ are alone contracted; consequently, transverse furrows are formed across the middle part alone of the forehead. The skin over the exterior parts

FIG. 316.—Case XXVII., Chronic Melancholia. Morbid and uninhibited expression of grief. Darwin's "grief muscles" in contraction producing "horseshoe mark." (From photograph taken by author.)

of both eyebrows is at the same time drawn downward and smoothed by the contractions of the outer portions of the orbicular muscles. The eyebrows are likewise brought together through the simultaneous contraction of the corrugators; and this latter action generates vertical furrows, separating the exterior and lower part of the skin of the forehead from the central and raised part. The reunion of these vertical furrows with the central and transverse furrows produces a mark on the forehead which has been compared to a horseshoe; but the furrows more strictly form three sides of a quadrangle. They are often conspicuous on the foreheads of adults, or nearly adult persons, when their eyebrows are made oblique; but with young children, owing to their skin not easily wrinkling,

FIG. 317.—Case LV., Acute Melancholia. Marked and characteristic innervation of Darwin's "grief muscles." Intense motor disturbance. (From photograph taken by author.)

they are rarely seen, or mere traces of them can be detected" ("Expression of the Emotions in Man and Animals," by Charles Darwin, Am. ed., 1873, p. 181).

This peculiar contraction of the "grief muscles" receives its best illustration in states of mental depression, but irregular and morbid activity of the brain-cells in different forms of insanity may produce nearly the same action, even though the state of mind is one of complete confusion or even exhilaration. In Case XXVII., chronic melancholia, we see the action of Darwin's "grief muscles" producing in a striking degree obliquity of the eyebrows and the vertical lines between them which Darwin says is so characteristic of emotions of depression. In this same case the naso-labial furrow, extending from the wing of the nose to the angle of the mouth, and which Darwin says is of so frequent occurrence in blubbering children, is strongly marked. In Case LV. this peculiar action of the corrugators and central fasciæ of the frontalis muscle is strikingly illustrated. The corrugators in their contraction draw the eyebrows inward, producing the vertical furrows seen at the inner edge of each eyebrow; the frontalis in its contraction produces the transverse furrows across the centre of the forehead, while the orbicularis in their contraction smooth out these transverse wrinkles on the outer borders of the forehead. As in the previous case, the naso-labial furrow and the depression of the corners of the mouth, due to the contraction of the *depressores anguli oris*, are very pronounced. Indeed both Cases XXVII. and LV. afford most strik-

ing representations of prolonged concentrated grief and mental suffering. These are typical cases of melancholia, and while it is evident that emotions of depression have produced their normal and legitimate expression in their faces, it is equally plain that no person in a state of mental health would present this remarkable appearance for several consecutive hours, and in the presence of others. Such action as is represented in the photographs of Cases XXVII. and LV. could only proceed from persistent and uninterrupted morbid cell activity. In health, the normal inhibitory action of the cortical centres would render such extreme manifestations impossible. In these cases of melancholia no amount of persuasion or distraction, not even the fact of sitting for a portrait, when most people make an effort to smooth out their features, produces the slightest change in these disturbed and painful countenances. It is quite obvious that healthy inhibition has ceased to be a factor in the facial expressions of these unhappy subjects, and that the various muscular contractions of their faces are so many persistent signals of the psychic pain which fills their minds. The photographs figured in Plate IX. of Kirchoff's work (Figs. 318, 319, and 320 of the present article) illustrate the uninhibited expression of distress in the facial region of a case of paralytic dementia, upon an imperfect attempt to articulate a difficult word, and the smoothing of all the muscular folds when the patient is in repose.

FIG. 318.—Paralytic Dementia. Face in repose. (From Kirchoff's Handbook.)

FIG. 319.—Paralytic Dementia. (Same case.) Uninhibited expression of distress as shown in the contraction of the "grief muscles" upon attempting to articulate a difficult word. (From Kirchoff's Handbook.)

In the portraits of cases of acute mania it is very plain that inhibition exercises no restraining influence whatever over the constant nerve-muscular activity which so transforms the physiognomy. Case XLII. (see p. 519) illustrates how completely has intelligent control over the features been swept away by the storm raging within the cerebral centres.

The faces of the chronic delusional insane show quite clearly the absence of healthy inhibition. Thus the sly, distrustful glance, the bitter, lowering look of hatred and enmity, the self-satisfied air of exaltation, or the dejected countenance of self-abasement, are expressions quite frequently noted among this class of insane, and are another evidence of the inability of the patient, through impaired inhibition, to control the outward manifestation of the inner feelings. These same feelings exist in health, oftentimes with great intensity, and yet how perfectly are they concealed! In this connection it is interesting to note that in the weaker mental conditions of childhood these same feelings and emotions are frequently and as clearly represented in changes of facial expression as are the corresponding emotional states in the faces of the adult insane. The main difference lies in this fact, however, that in childhood inhibition through the will has not been developed, while among the adult insane it has been weakened by disease.

FIG. 320.—Paralytic Dementia. (Same case; conditions the same as in Fig. 319.) (From Kirchoff's Handbook.)

FIG. 321.—Case III., Chronic Delusional Insanity. Persistent, uninhibited ideas of suspicion and hostility. (From photograph taken by author.)

Case III., characterized by chronic delusions of enmity and suspicion, and also homicidal, quite clearly expresses in the countenance the dissatisfaction with, and the opposition to, those about him, as well as fierce determination to gratify his impulses on the first favorable opportunity.

Case XII. quite plainly manifests in his countenance his all-absorbing egotism. In sitting for his portrait he chose his own position, arranging with great care his decorations, consisting of old buttons, bits of glass,

FIG. 322.—Case XII., Paranoia. Morbid egotism and fondness for display. (From photograph taken by author.)

brass wash-bowl chains, tin, etc., which he imagined to possess great value. The violin, which he made himself out of limited materials, and with an old knife and awl, he was anxious to display as a Cremona instrument of rare worth. The inconsistency of his real position (that of confinement for life in an asylum), the utter worthlessness of his jewelry and improvised insignia do not in the least lead to the inhibition of the expressions of morbid vanity and self-importance which pervade his countenance. Indeed, in nearly all forms of acute or chronic insanity, characterized by active persistent ideas, there will be noticed in the facial expression a complete abandonment to the prevailing morbid emotions, with scarcely any attempt at inhibition.

FIG. 323.—Case of Paranoia. Uninhibited expression of opposition and resentment. (From Kirchoff's Handbook.)

Kirchoff's views of insane patients in Fig. 331, Fig. 332, Fig. 325, and Fig. 326 illustrate how completely the insane abandon themselves to the predominant sentiments that characterize their individual cases. Fig. 329 is especially interesting, in that the same individual is shown under more normal conditions. Impaired inhibition explains all this distortion of feature.

A peculiar appearance of self-abstraction is the second way in which weakening of the inhibitory power among the insane manifests itself.

This self-absorption results from inability of the patient to inhibit trains of morbid and irrelevant thought. He looks preoccupied, and often entirely disregards his environment. So absorbed does he become that it is with the greatest difficulty that he concentrates his attention on persons or things about him. Hence results an expression of indifference, a fixed intent gaze, but with no particular object within the range of vision. In discussing the position and condition of the eyes in the countenances of the insane more extended allusion to this subject will be made. At present it is only necessary to call attention to the fact that the peculiar absorbed, absent-minded expression, so frequently met with in the insane, is due to impairment of the faculty of attention caused by weakening of the power of inhibition. In Figs. 333 and 334, taken from Kirchoff's work, this absorbed expression, indicating complete disregard of the environment, is well preserved.

FIG. 324.—Case of Paranoia, Showing Disappearance of all Healthy and Natural Expression, Due to Absence of Cortical Inhibition. (From Kirchoff's Handbook.)

III.—The third manner in which the physical expression of health is modified by insanity is through *excessive, deficient, or automatic nerve-muscular activity of an involuntary character, dependent upon morbid irritation or degeneration of the cerebral cell-structure.* Allusion has been previously made to that regular transmission of nerve-force which, in conditions of health, is constantly passing from the cerebral centres to the muscular periphery. The results of this elimination of nerve energy are seen in that permanent and normal tension of the muscular system called muscular tonicity, and also in the ordinary facial expression of every individual when the features are in repose. It is proposed in the present section to consider how this normal and regular transmission of nerve energy in health is modified by

FIG. 325.—Case of Mania, Showing Uninhibited Muscular Movement. (From Kirchoff's Handbook.)

the functional and organic disturbance of the brain in insanity. In doing this we enter the larger field of Physical Expression, where we study not only the changes observed in the face, but every abnormal manifestation taking place in the entire muscular system, including gesticulations, attitudes, manner of holding the head, carrying the hands, and every possible irregular and abnormal muscular movement.

Fig. 326.—Case of Mania. Uninhibited egotism and exhilaration. (From Kirchoff's Handbook.)

All these movements, which are caused by irregular cell activity of the cerebral centres, have one characteristic distinguishing them from the ordinary changes of facial expression: they are entirely meaningless, subserve no purpose, and do not conform to any of the well-known expressions of the emotions, as grief, joy, etc. In health the expression of these emotions is always recognized by certain well-known muscular contractions which observation has taught us are characteristic of corresponding mental states. We know, for instance, that laughter will be manifested by contraction of the *corrugators*, of the *malaris*, and of the *great zygomatic*; in grief we know that the eyeballs will be rolled a little upward and inward, and that the contraction of the central fibres of the *frontalis* acting upon the *corrugators* will produce a peculiar and very characteristic wrinkling of the forehead above and between the eyes, and that the *depressores anguli oris* will draw down the corners of the mouth. These muscular contractions follow in a certain definite manner their causative mental states. So regularly and constantly do they succeed their antecedent mental conditions, that, given the state of mind, the resulting movements of expression can be foretold even before their appearance. Hence the expressions of the emotions can be easily separated into groups: thus we have the expression of joy, grief, disgust, and all the others.

Fig. 327.—Case of Mania; showing unrepressed expression of exhilaration. (From Kirchoff's Handbook.)

On the other hand, the movements under discussion are not regular, do not indicate any particular state of mind, but represent rather that irregular and interrupted action of the brain-cells which often takes place in acute insanity, and is of very frequent occurrence in the degenerative brain conditions of chronic alienation.

To avoid confusion we may study this phase of the Physical Expression of the insane under three heads:

I. As representing states of excessive nerve-muscular activity due to central irritation.

II. As representing states of deficient nerve-muscular activity due to central degeneration.

III. As representing states of automatic cell-activity in the cerebrum occurring not infrequently in acute insanity, and quite constantly in the chronic form of the disease.

1. *Physical Expression of the Insane Caused by Excessive Nerve-muscular Activity.*—That mysterious property which, for want of a better name, we call nerve-force, is undoubtedly being constantly stored up within the brain-cells, and as regularly discharged from them. The intimate relationship between this elimination of nerve-force and muscular movement has been clearly stated by Dr. Carpenter, in the following paragraph:

Fig. 328.—Case of Mania; showing unrepressed expression of exhilaration. (From Kirchoff's Handbook.)

"We shall hereafter see that each kind of mental activity—sensational, instinctive, emotional, ideational, volitional—may express itself in bodily movement; and it is clear that every such movement is called forth by an active state of a certain part of the brain, which excites a corresponding activity in the motor nerves issuing from it, whereby particular muscles are called into contraction. No physiologist can doubt that the mechanical force exerted by the muscles is the expression of certain chemical changes which take place between their own substance and the oxygenated blood that circulates through them; or that the nerve-force which calls forth those changes is intimately related to electricity and other physical forces.

But this nervous activity has its source in molecular changes in the nerve-centres; the transmission of nerve-force along the motor nerve being just as dependent upon chemical changes taking place between the substance of the ganglionic centre from which it proceeds, and the oxygenated blood that circulates through it, as is the transmission of an electric current along the

Fig. 329.—Folie Circulaire. A, Depressed stage, with expression of uninhibited grief. (From Kirchoff's Handbook.)

telegraph wire upon the chemical changes taking place between the metals and the exciting liquid of the galvanic battery" ("Mental Physiology," Am. Ed., 1874).

The laws which govern this elimination of nerve-force are similar to the laws governing force in general. The great law of conservation of force or energy prevails in the field of cerebral activity as elsewhere. When chemical changes take place within the delicate nerve-centres of the brain as a consequence of external stimulation through the senses, or internal stimulation following mental activity, the result conforms to the requirements of this universal law. Either the force generated by these chemical changes remains stored up in the cerebral cells as potential energy to be called forth at some future time by stimulation, or it is transferred from the cells along the proper tracts to the muscular system, and appears as motion. This is the physiological definition of Physical Expression.

Fig. 330.—Folie Circulaire. *B*, Exhilarated stage, when countenance has returned to a more normal condition. (From Kirchoff's Handbook.)

Now, a certain constant and regular transmission of this nerve-force from the central cells to the muscular periphery is, as we have seen, natural and in accordance with health. Indeed, a state of general good health demands this outward relief for the potential energy constantly accumulating within the brain-cells. Thus the excessive muscular activity of all young and growing animals, the playfulness of young dogs and kittens, the pranks and follies of boyhood, are oftentimes merely the expression of this great natural law. In adult life the potential energy of cerebral cells is manifested in more practical and useful ways, but still in the most tangible results of a successful business, mechanical or professional life, we recognize the outward manifestation of the potential energy which has been stored up within the brain-cells until the proper stimulation called forth its discharge.

Fig. 331.—Case of Periodical Melancholia. (From Kirchoff's Handbook.)

This intimate relationship between muscular movement and central cell-activity within the cerebrum, has been discussed in Dr. Francis Warner's interesting volume on "Physical Expression," and in a recent article by the same author in the *Journal of Mental Science* for April, 1889. This author calls attention to the fact that these outward manifestations of central cell-activity begin at birth, and are witnessed in the countless random and meaningless movements of infancy, to which he has given the name of *mikrokinesis*. Undoubtedly at a very early age healthy inhibition of muscular movement begins. One by one useless and superfluous movements are checked, eliminated, or co-ordinated in such a way that when adult life is reached, the individual, if in health, manifests those muscular activities which subserve the general purposes of the will and intelligence.

Fig. 332.—Case of Periodical Melancholia. (From Kirchoff's Handbook.)

Even at this period of life many movements remain, fulfilling no particular purpose, but representing mere automatic cell-activity which has either been acquired by the individual or transmitted to him by heredity. The various movements of the facial muscles, including the tonic contractions already referred to, and which, in their totality, form the individual physiognomy, belong to this automatic and acquired class.

In diseased conditions of the brain, however, the pathological irritation of these delicate nerve-centres may be so great as to overcome any acquired inhibitory resistance, and thus liberate an excess of nerve-force which will seek an outlet in the usual way by passing along the efferent motor tracts to the muscles, and there appearing as muscular movement. Thus it is that in the functional or organic brain disturbances of insanity, abnormal motor activities are a frequent accompaniment of disturbed states of mind.

Fig. 333.—Case of Dementia. Ocular divergence due to suspension of the attention and lack of ideation. (From Kirchoff's Handbook.)

Pathological motor activity is, as we have seen, spasmodic, irregular, and purposeless. The most striking illustration of this fact is afforded by cases of chorea and epilepsy. There seem to be good reasons for supposing that in these diseases the brain-cells are in an unstable condition, owing to hereditary, traumatic, or nutritive

disturbances, and that, as Gowers says, the discharge of these same cells "may depend on the production of force within being increased in excess of the resistance, or on the resistance being duly lessened" ("Epilepsy and other Chronic Convulsive Diseases," p. 213).

In the active stages of mania and melancholia, in the acute excitement which sometimes occurs in paresis and other organic diseases of the brain, this same discharge of nerve-force takes place. The unceasing jactitation of acute mania, the restlessness of melancholia, are familiar illustrations. Such patients are apt to be in a state of constant muscular activity, pacing the floor, tearing their clothing, and destroying whatever comes in their way.

FIG. 334.—Case of Melancholia. Self-absorption, ocular divergence, and contraction of "grief muscles." (From Kirchoff's Handbook.)

These irregular and motiveless movements of the insane are earliest manifested in the facial muscles. The extreme sensitiveness of this region to cerebral conditions, and the weaker inhibitory control which the brain possesses over these delicately poised muscles, are reasons why the face so often presents the first physical manifestations of the advancing mental disease. Very frequently the muscular disturbance does not extend beyond the face; but it is quite rare that this region does not show some evidence of the morbid irritation of the brain-cells. When the face alone is disturbed in this way, the resulting expression is quite peculiar, and resembles those meaningless contractions that are produced when a mild galvanic current is passed through these muscles. The muscles are gently but continuously contracted, particularly those about the forehead, at the root of the nose, and about the mouth, giving to the patient a peculiar kind of *troubled* or *anxious* expression. It is often noticed by the friends at a very early stage of the disease, and they will tell you that the patient does not look natural, that his countenance has a strained, intense look, quite different from his normal expression, but still very difficult to describe.

FIG. 335.—Case XXXIX. Acute Mania. *A.* As he appeared on arrival at asylum from prison. Morbid innervation of facial muscles. (From photograph taken by author.)

This particular region about the forehead, above and between the eyes, and at the root of the nose, is the first to bear evidence of psychic pain or distress, and, indeed, of mental excitement of any kind. Nearly all writers on physiognomy speak of the important rôle sustained by the frontal region in the development of facial expression. Some attribute this fact to the nearness of the part to the regions of thought and mental activity in the brain, and cite as one evidence of this the fact that we all involuntarily rub or press this space above and between the eyes when we are perplexed. The act of rubbing relieves, in some way, the unpleasant tension which we feel at such times. It is not at all improbable that the nerve-force, liberated by the increased activity of the anterior convolutions of the brain during active thought, is transmitted from the cortical centres to these muscles and occasions that slight feeling of tension, which is undoubtedly relieved by rubbing.

The peculiar action of the "grief-muscles" in melancholia has already been discussed. It is somewhat singular that these same muscles are called into action in other states of mind than those of morbid depression. States of mental confusion, of mania, with exhilaration, often stimulate the grief-muscles into activity. Illustrations of this are afforded by Cases XXXIX. Fig. 335, A) and XLII. (Fig. 337, A). In these last cases

FIG. 336.—Case XXXIX. *B.* Taken at time of discharge and recovery. Disappearance of morbid innervation, improved nutrition. (From photograph taken by author.)

we may believe that the cell irritation of the cortex transmits nerve-force in the direction of the so-called grief-muscles, since, through repeated use, that channel affords the readiest outlet. Or, it may be that this disturbed and anxious look so often seen in different phases of insanity is due to a feeling of displeasure awakened in the mind of the patient by the opposition to his plans and delusions, which he so frequently encounters in those about him; and this sense of displeasure and disappointment has its usual manifestation in the muscles that reflect these emotions. However this may be, the frontal region, including the eyes and space between them, is, through contiguity to the brain, the most expressive part of the face, and the nerve-muscular activity of insanity finds there its earliest and most persistent reflection.

Returning to the illustrations, we find that the portraits of Cases XXXIX. and XLII. illustrate the peculiar muscular contractions already referred to, and which proceed from the brain irritation of *mania* in different degrees of intensity. Case XXXIX. was transferred to the asylum from the prison. Six weeks before his removal to the asylum he began to be careless in his work,

and was supposed to be refractory. He was placed in solitary confinement, but while in this situation he began to develop hallucinations of sight and delusions of exaltation, thinking he was Christ. On his arrival at the asylum he was quite deluded, slightly incoherent, and exhilarated. Fig. 335, A, shows his appearance at this time. The compressed lips, the almost bristling hair, deep furrows in the skin extending from the alæ nasi to the corners of the mouth, the lowered eyebrows, and deep wrinkling between the eyebrows at the root of the nose and on the forehead, illustrate what has been referred to as a "troubled" expression, and show how the centric irritation has been communicated to the muscles of the face. Fig. 336, B, giving the face of the same individual at time of recovery, presents a most marked contrast. The smooth brow and forehead, the clear, open eye, and natural position of the mouth, all indicate, more clearly than words can express, the subsidence of the storm within the cerebral centres.

Fig. 337.—Case XLII., Acute Mania. A. Taken during active stage. Morbid innervation, trophic alterations, neglect of personal appearance. (From photograph taken by author.)

In Case XLII. (Fig. 337), the patient was entirely incoherent, and in a state of constant muscular agitation. He was destructive, and almost too confused to eat his meals, so that frequent feeding with the nasal tube became necessary. The staring eyes, wrinkled forehead, dry, dishevelled hair, and torn coat are in striking contrast with Fig. 338, B, in which the hair has assumed its natural condition, the face is smooth, and the eyes are calm and quiet.

In cases of melancholia with motor disturbance we see the effects of central irritation reflected in muscular agitation. Sometimes the patient will pace the floor wringing the hands, groaning and moaning, or the excitement will become so intense as to lead to an impulse to tear or destroy whatever comes within reach.

In many cases of chronic insanity almost constant tooth-grinding is a noticeable feature, and another illustration of morbid transmission of nerve-force from the central cells to the muscular periphery. Tooth-grinding is not uncommon in nervous children, and is of very frequent occurrence in the insanity proceeding from structural brain disease. It is noticed oftener in connection with paresis than with any other disease. In passing through wards for demented patients it is a familiar sound, and sometimes is made with such force that it can be heard at a distance of thirty or forty feet. Warner thus alludes to this symptom: "Tooth-grinding is produced by the action of the deeply situated pterygoid muscles; champing of the jaws is produced by the masseter and temporal muscles; all these muscles are supplied by the fifth nerve, and it is to their condition that we must look for information as to the condition of the central origin of the nerve." By means of the Casserian ganglion and small nerve-filaments branching from it, the fifth nerve is brought into intimate connection with the dura mater and adjacent membranes. In chronic insanity associated with dementia these membranes are nearly always found to be in a pathological condition. It is quite natural, therefore, that morbid sensations should be transmitted from these diseased membranes, through the sensory branches of this portion of the fifth nerve, back to its origin in the pons varolii and medulla, and thence be reflected outward along its motor tract to the pterygoid and masseter muscles.

In many cases of maniacal excitement attention has been called to the dry, rough, and almost bristling condition of the hair. In those patients who have recovered from mania the hair resumes its normal condition, is softer, and more easily kept in place. Illustrations of this are seen in Cases XXXIX. (Fig. 335) and XLII. (Fig. 337). In chronic, or in recurrent mania the dry and bristling state of the hair is of common occurrence. One case under the writer's observation, a woman, was characterized by exacerbations of excitement, and at these times her hair was exceedingly dry and stood out in a striking way all about her head and face. In two cases the hair was naturally curly but, as one result of the active mental excitement, there seemed to be imparted to it a stiffness quite different from that produced by the curliness; each individual hair, during the period of excitement appeared to have a special prominence of its own.

This singular condition of the hair, in states of active mental excitement, has been alluded to by Darwin in his "Expression of the Emotions in Man and Animals." His explanation, which is undoubtedly correct, affords another illustration of excessive nerve-muscular activity following cerebral cell irritation. Every hair-sac is provided with delicate unstriped muscular fibres—*arrectores pili*. These minute involuntary muscles are exceedingly liable to contract under the influence of strong emotions, such as fear and anger, as well as from the effects of cold. The contraction of these muscles causes a more or less complete erection of the hair shaft. Darwin concludes that "the erection of the dermal appendages is

Fig. 338.—Case XLII., B. Taken at time of recovery. (From photograph taken by author.)

a reflex action, independent of the will; and this action must be looked at when occurring under the influence of anger or fear, not as a power acquired for the sake of some advantage, but as an incidental result, at least to a large extent, of the sensorium being affected" (Op. cit., p. 102).

In the active mental excitement of mania, acute or chronic, persistent irritation of the cerebral cell-structure leads to the transmission of nerve-force along this channel to the *arrectores pili*—all the more readily because the natural emotions of fear and anger have made this a customary route. Hence in those forms of insanity which are accompanied by excessive nerve-muscular activity this erection of the hair is an almost inevitable result. This condition of the hair is only seen in those forms of mental disease characterized by active excitement, or marked emotional disturbance. The bristling and erection is intensified by the dryness and roughness of the hair due to the impaired action of the subcutaneous glands. Darwin also informs us "that with man the hairs on the front of the head which slope forward, and those on the back of the head which slope backward, are raised in opposite directions by the contraction of the *occipito-frontalis* or scalp muscle" (Ibid., p. 297). This muscle is, as we have seen, often kept in a state of unnatural tension in conditions of pathological cerebral excitement, and hence its action would assist the *arrectores pili* in maintaining an erect and bristling state of the hair.

The study of the portraits calls for a slight digression on the significance of the wearing apparel of the insane. When we consider its neglected, disarranged state, its unique and oftentimes bizarre arrangement; when we contrast the general appearance of the clothing of many of the acute and chronic insane with what we know is characteristic of mental health, then we become impressed with the fact that this matter of the condition and arrangement of a patient's clothing may be of diagnostic or even prognostic value to the alienist. Even in health our estimates of individual character are assisted by observation of the condition and general style of a person's clothing, so closely related to our inner selves have these outer vestments become. Carlyle, in "Sartor Resartus," made no mere imaginative allusion when he asked the question:

"How, then, comes it, may the reflective mind repeat, that the grand tissue of all tissues, the only real tissue, should have been quite overlooked by science, the vestural tissue, namely of woollen or other cloth; which man's soul wears as its outmost wrappage and overall; wherein his whole other tissues are included and screened, his whole faculties work, his whole self lives, moves, and has its being?"

In observing the condition of the clothing of the insane we shall have additional evidence for believing that this "outmost wrappage" may partially reflect the mental and moral state of the individual. For this reason no especial attempt was made in the taking of the various portraits to arrange the wearing apparel for appearance' sake. Many of the views reproduced in this article were taken in the ward, so as to secure a true likeness of the individuals as they appeared at that particular moment.

In all forms of mental disease accompanied by motor disturbance due to excessive and irregular transmission of nerve-force from the brain-cells, we find that the resulting muscular agitation causes the clothing to be disarranged and disorderly, oftener it is torn and partially destroyed. In acute mania, and in the melancholia accompanied by restlessness, the cases to which we have already referred illustrate what has been said about the condition of the clothing. One of the great difficulties encountered by asylum officers is the tendency manifested by the active insane to tear and disarrange their clothing. This is only one way in which nerve-force, generated in excess of inhibitory resistance, seeks an outlet.

In cases of mental failure, such as dementia proceeding from chronic insanity and organic brain disease, the clothing shows neglect, is often untidy unless personally cleansed by another, and seems to hang from the person rather than fit his form. A party of demented patients may be recognized at a distance by the very hanging of their clothing. The absence of healthy muscular resistance, the sluggish gait, drooping shoulders, pendent arms and hands, give to the outer garments a peculiar and almost indescribable appearance, which once recognized cannot be forgotten. It would seem as though the general lack of healthy muscular tonicity, the flabby state of the entire muscular system, characteristic of this form of mental disturbance, had been communicated to the clothing.

The subject of personal attire among the insane should not be dismissed without a passing allusion to the penchant which many of this class exhibit for fantastic dress. In some forms of subacute mania, of the active stage of recurrent mania, or in some cases of mild chronic mania, and noticeably among many of the chronic delusional insane, there is quite frequently exhibited a passion for bright colors, and for personal decoration of a fantastic character.

Artists and dramatists, from the earliest times, have always heightened the effect of their portrayal of insanity by representing the insane as peculiarly decorated with straw, flowers, feathers, or rags. Thus Shakespeare makes Ophelia enter "fantastically dressed with straws and flowers." And in King Lear, Cordelia, when reflecting upon her poor insane father, says:

> "Alack 'tis he; why, he was met even now
> As mad as the vex'd sea, singing aloud;
> Crown'd with rank fumiter, and furrow weeds,
> With hardocks, hemlock, nettles, cuckoo-flowers,
> Darnel, and all the idle weeds that grow
> In our sustaining corn."

Aside from all exaggeration due to the license universally granted the poet and painter, there is an actual scientific foundation for this time-sanctioned portrayal of insanity. It is a matter of common occurrence in asylums for the insane to see patients, suffering from the above-mentioned types of the disease, pick up shining bits of tin, brass, or glass, or brightly colored cloth, and use the same as a decoration for the hair or clothing. Such patients often attach a great value to these worthless materials. While it cannot be said that this tendency for fantastic decoration is always an indication of chronic insanity, it is frequently associated with that form of mental disease. Nearly every asylum contains, among its old residents, some who have made themselves conspicuous for years by the odd and fantastic decoration of their dress; and were it not deemed inadvisable to allow this passion for odd display to be carried too far, such cases would be far more numerous and their costumes much more striking than is usually the case.

Cases XII. (see page 515) and LIV. illustrate the tendency for striking and fantastic display, notwithstanding that in each of these patients an attempt was made to reduce it to a minimum. Case XII., one of chronic mania or paranoiac insanity, manifested a marked fondness for sensational display. In sitting for his portrait he arranged his regalia with the greatest care, wishing that his various pins, "precious stones and diamonds," as he called them, should all be included in the photograph. Case LIV., chronic mania with marked delusional exaltation, always decorated herself in some fantastic manner. At the time the portrait was taken she had evidently taken the greatest pains to produce an effect with her hair and also with the handkerchief which is elaborately displayed on her dress. The peculiar cap was made out of worsted and cotton cloth ravellings, and was considered by her to be a very choice ornament, and in some way a badge of her superiority. She entertained the delusion that she was Christ, the Virgin Mary, and that she had unlimited power. The portrait of this patient is also interesting as showing the marked inhibitory control that exists in the midst of great incoherence of idea and language. No sane person could prove a better poser for her photograph than this very excitable insane woman.

The variety of fantastic decoration that one meets in an asylum is almost endless. The interesting query suggests itself whether this singular fondness for adornment

noticed among the insane is anything more than an exaggeration of a natural proclivity common to mankind generally. In health the desire for personal decoration has certain well-defined limits prescribed by fashion and common sense; but as a result of mental disease this same natural desire is no longer controlled by a healthy judgment and inhibition, and hence this fantastic, grotesque, and odd display.

II. *Physical Expression of the Insane Caused by Deficient Nerve-muscular Activity Due to Central Degeneration.*—Deficient nerve-muscular activity plays a prominent part

FIG. 339.—Case LIV. Chronic Mania. Showing exaltation, fantastic decoration, etc. (From photograph taken by author.)

in the etiology of the physical expression of insanity. A recognition of its existence in any case frequently enables the physician to make a correct diagnosis and prognosis of the mental disease affecting the patient. In nearly all forms of chronic insanity accompanied by mental enfeeblement, deficient nerve-muscular activity corresponds to the degree of mental impairment.

Dementia is the sad termination of all chronic, as well as of many of the acute, insanities. The degree of the dementia varies with individuals, and no definite rule can be given which will indicate just how rapidly or to what extent mental weakness will advance in any particular case.

Sometimes the impairment of mind is very slight, the individual not being incapacitated from living at home and enjoying a fair amount of personal liberty, and performing many acts of life fairly well. Again, the deterioration of mind is such that the patient is incapable of sustaining the responsibilities of life outside an asylum, and yet is made very comfortable by the regularity, intelligence, supervision, and mild restraint of the hospital. Indeed, under careful direction, such patients come to be capable of performing a certain amount of fairly skilled labor. In still other cases, however, the mental impairment has advanced so far that not only is the hospital the only proper and safe residence for the patient, but his entire life in such an institution is helpless and unproductive. He becomes a veritable wreck in which only the slightest semblances of mind can be detected, nearly all the acts of whose life have become purely automatic and vegetative.

Some of these varying degrees of mental weakness are noticeable in nearly all cases of persistent and long-continued insanity, and many cases of acute insanity do not recover so perfectly but that a slight amount of mental damage may be detected. Unfortunately, our knowledge of the pathological anatomy of the brain is so limited that we cannot with precision locate the specific lesion corresponding to the various forms of mental disease. It is generally assumed that the pathological condition is one of degeneration consequent upon hyperæmic and inflammatory processes, or upon inflammatory changes succeeding malnutrition of that delicate organ.

Whatever the pathological alterations in the brain-cells may be, varying degrees of motor impairment constitute one very constant result in all cases of chronic insanity attended with mental weakness. We have already noticed how excessive nerve-muscular activity characterizes nearly all attacks of acute mania, as well as the excited stage of paresis, and the temporary exacerbations of excitement occurring in dementia. In these cases the nerve-force is discharged in excess of the power of resistance, either because the inhibitory power itself is diminished, or because there is an excess of nerve-force generated within the nerve-centres. On the other hand, in cases of persistent and long-continued acute insanity, as well as in chronic insanity associated with the varying degrees of dementia above mentioned, deficient nerve-muscular activity is a prominent symptom. And the inference seems a legitimate one, that this deficient nerve-muscular activity represents or corresponds to certain degenerative processes occurring within the brain-cells. This deficient nerve-muscular activity varies from the slightest motor impairment in a few of the delicate facial muscular strands, to an extreme degree of general muscular paresis.

Griesinger says: "The most important circumstance in regard to anatomical diagnosis and to prognosis is the existence or non-existence of *severe motory disorders*, in particular, of general progressive paralysis." We might add that the slighter motor impairments have a very important bearing upon the diagnosis and prognosis of the patient's mental condition. In nearly all cases of dementia secondary to acute or chronic mental disease, there are evidences of this motor impairment. It is not unlikely that if we possessed instruments for accurately ganging the degree of intensity of motor force in individual muscles in patients suffering from dementia, we should find a much larger deficiency than we realize by our present methods of observation.

This deficient nerve-muscular activity represents imperfect or weakened innervation on the part of the central organ—the brain. All nervous tissue is endowed with one peculiar property, that of *sensibility*. By means of it, "the nerve-cells feel excitation from without, and react in consequence, by virtue of the excitement of their natural affinities" (Luys, "The Brain and its Functions," p. 81). Impaired sensibility of the nerve-cells is a frequent result of protracted attacks of acute insanity, and a constant accompaniment of the various forms of dementia. And in such cases there is imperfect reaction to the various sensory stimulations which, in health, are being constantly transmitted from the periphery to the higher nerve-centres of the brain. Dementia is characterized by imperfect responsiveness to external impressions. It is difficult to arouse and interest such patients. They care little for their surroundings; they eat and sleep, but their energy seems lost. They lie or stand around in a listless way, and oftentimes it is necessary to speak to them in a louder voice in order to attract their attention.

Impaired nervous sensibility is attended with imperfect motor reaction, probably for the reason that the afferent and efferent tracts do not transmit impulses to and from the brain as readily as in health, and also because the brain-cells themselves are less sensitive. Those regions which, in health are most responsive to this excitation are very apt to be the first to become affected in diseases of the central nervous system. For this reason the face, in the earliest stages of dementia, begins to show evi-

dences of impaired innervation. The lines about the eyes, the forehead, and the mouth, which were formerly well defined and which represented the healthy muscular tonicity already referred to, begin to lose their precision and appear to be smoothed out. The peculiar pose of the features, due, as we have seen, to the continuous transmission of nervous force along the various efferent nerve-tracts to the muscular periphery, and which gives what we call character to each individual countenance, seems to have lost its definiteness. As a result the face begins to lose its expression, and in the very earliest stages of the disease constitutes a painful symptom for the friends to behold, and leads the physician to make a grave diagnosis and prognosis.

This defective nerve-muscular activity, which is first manifested in the faces of demented patients, in time extends to the larger muscles of the extremities. Demented patients become clumsy, and if good mechanics, gradually lose the muscular precision which formerly characterized their work. Quite frequently such individuals are obliged to give up a certain line of skilled labor in which they formerly excelled, and undertake a less exacting branch of the work, or renounce it entirely before it becomes fully apparent that their mental health is being seriously undermined. At a still later stage of the disease the muscles of locomotion become impaired, and the patient grows clumsy in gait.

In the wards for demented patients in a large asylum, one is struck with the slow, lumbering gait of the patients, with their lifeless attitudes and the general absence of healthy muscular activity which is evident on every side. A party of demented persons is easily recognizable at a distance. Their muscles, like their clothing, seem to *hang*, and there is none of that elasticity of movement characteristic of health.

This progressive muscular failure is quite noticeable in the cases of terminal dementia, which constitute so large a proportion of the population of public hospitals for the insane. Oftentimes these patients are under observation for years. In the earlier stages of their asylum residence they are capable of performing much manual labor. Gradually, as their dementia advances, they become less capable of sustained work; they may grow fleshy, but their muscles become weaker and more unreliable; and finally they cease to be efficient workers, and spend their time in the ward or on the grounds, lying and lounging about in a listless way. In these cases there is a real failure in nerve-muscular force, which is represented by an inability to enter into mechanical employment, as was formerly their wont.

In cases of structural brain disease the order in which failure of muscular innervation occurs is quite interesting, and has already been referred to. First the muscles about the mouth begin to show weakness; then those about the forehead and between the eyes; later, the articulation begins to fail and to grow more thick and indistinct; and the muscles of deglutition respond so feebly to innervation that the act of swallowing is rendered clumsy and difficult, and the patient is in danger of choking. Finally, the larger muscles of the extremities begin to weaken; the drooping head, shoulders, and arms, and the shuffling, clumsy gait indicate the steady progress of the brain disease.

Warner says: "In a strong and healthy man the head is held erect and symmetrical, unless some central condition or external agent changes the posture. In a strong man the centre of the forehead is in the mid-plane of the body, the antero-posterior and the transverse axes are horizontal, with both eyes on the same level; this is a normal position of quiescence" ("Physical Expression," International Scientific Series, p. 185).

In cases of progressive dementia, in the advancing stages of paresis, this failure of innervation is quite commonly seen in the drooping of the head.

In many cases the lower jaw drops on account of relaxation in those muscles which support it; this gives to the face an elongated expression, and quite frequently occasions the open, stupid-looking mouth so often seen in dementia (Fig. 340).

Defective innervation, as we have seen, finally extends to all the muscles, and produces that peculiar drooping of the body, shoulders, arms, and even fingers, and that almost indescribable, but when once seen never-to-be-forgotten, clumsiness of gait and attitude so characteristic of demented patients.

III. *Physical Expression of the Insane, Caused by or Representing States of Automatic Cell-activity in the Cerebrum, Occurring not Infrequently in Acute Insanity, and Quite Constantly in the Chronic Forms of the Disease.*—The subject of automatic nerve-activity is so well understood that any extended allusion to it would be superfluous. It has been a matter of frequent physiological observation, that all nerve-structure manifests a tendency toward automatic activity. This attribute inherent in nerve-tissue is noticeable in the lowest forms of animal life possessing only the simplest and most rudimentary suggestion of a nervous system. The ascidian illustrates the peculiar mechanical and automatic action of a very simple organism that is wholly unprovided with anything like consciousness. In this animal crude, imperfect sensations are transmitted from its periphery through afferent nerve-fibres to a solitary ganglion; a motor impulse is thus originated in the ganglion, and, being reflected outward to the muscular fibres of the animal's outer sac and orifices, produces in these parts a simple contractile movement. This simple movement is entirely involuntary and reflex, and, upon the presentation of the proper stimulus, is always repeated in identically the same way, during the life of the ascidian.

Fig. 340.—Case of Progressive Dementia. Dropping of lower jaw on account of relaxation of the muscles which support it. (From Kirchoff's Handbook.)

As we ascend the scale of animal life the nervous system becomes more complicated; entire regions are specialized, one part becoming subordinate to another until we reach man, in whom the completest subdivision and specialization has been attained. In him the higher centres in the anterior cerebral region preside over the nerve-structures below, both in the brain and cord. But these more highly specialized centres of the human brain manifest the same tendency to automatic and mechanical activity.

In one respect, however, man differs from other forms of animal life. His *will-power* presides over and directs those various processes which in the lower animals are not only automatic and instinctive, but are largely involuntary. In man a few of the activities of organic life—such as respiration, the beating of the heart, and the like—are transmitted at birth fully established and are entirely independent of the will. Other processes, such as walking, writing, etc., are acquired after a most careful direction of the will and laborious practice, and then become automatic. Still other higher processes, such as the psycho-intellectual activities of the individual, while under the guidance of the will, conform to the universal law of automaticity. Thought runs in certain well-established channels, and "mechanism in thought and morals" is as susceptible of proof as the mechanical action of the heart or the lungs during the processes of

circulation and respiration—the only difference being that volition directs these intellectual and acquired activities.

A high volitional power, therefore, distinguishes man from the lower animals. Even the most highly developed of these lower orders possess limited volitional powers. In them life is largely automatic, and distinct purposive direction of their actions is slight. Many of their acts that seem to display a high degree of intelligence and to suggest the power of voluntary selection, prove, on close examination, to be merely the result of an unreasoning instinct which would not have admitted of any other course. In man, on the contrary, while his daily life is largely made up of various automatic activities, still the range of purposive selection is large, so that the "mechanism of thought and feeling" is made to serve the best interest of the individual through the guidance of the will.

In some way, at present obscurely understood, will-power and functional activity of the cortex are mutually interdependent. Hence disturbance of these centres in insanity, caused by impaired nutrition, defective functional activity, or more gross structural lesions, weakens the will-power of the individual. The functional activity of the cortical centres may be completely disarranged by insanity, and, as a result, the normal exercise of the will may be disturbed, if not entirely suspended. At the same time, however, the activities of the basal ganglia, no longer under the guiding and controlling influences of the cortical centres, continue automatically. As a result, purposeless thought and action of an automatic character is quite apt to follow those serious disturbances of the higher cerebral centres during attacks of severe acute and chronic insanity.

Automatic activity of the cerebral centres in health is subject to the direction of the will, and its results display purpose. Automatic activity of these same centres in disease of the mind seems to be less under the guidance of the will, and the resulting action appears purposeless. In proportion as the will-power is weakened by the brain disease, do meaningless automatic activities of thought and action prevail.

In passing through the wards for the chronic and demented insane, one is struck with the evidences on every side of automatic activity. Here you will notice a man walking backward and forward in a mechanical way for hours together, until he has worn a beaten path in the floor; there will stand one who picks away at a certain place on his clothing for an indefinite period, until he has worn the garment through to the skin. Quite frequently one will hear curious meaningless noises repeated in a mechanical way—singular repetitions of certain words or sentences wholly meaningless. It is not an uncommon thing for chronic patients to have some peculiar word or phrase, or even a single articulate sound, and to repeat it in an irrelevant way for years. In like manner you will meet with patients who make strange motions with the arms and hands, and take singular attitudes in a mechanical way. It is difficult to arouse the attention of such patients; their monotonous repetition of words and movements continues just the same, regardless of the presence of others, and with little reference to any attempts made for their diversion. All this variety of automatic action and speech would seem to indicate that the healthy functional activity of the higher cerebral centres has been disturbed and partially suspended, and that the lower centres are acting mechanically and without the normal volitional control.

Prolonged automatic activity in thought, speech, and action, among the insane, suggests a serious lesion in the higher brain. The more mechanical and purposeless the words and acts of the patient, the graver is the prognosis.

The nervous system manifests a striking tendency to mechanical repetition of any process once initiated within its centres. One epileptic attack is likely to be followed by another, and a number of seizures renders the prospect of still others quite certain, until in a short time the disease becomes firmly established. Both mania and melancholia manifest tendencies to repetitions of the attack, and each new attack renders the probability of another quite certain, until recurrency or permanent insanity is established.

In the advanced stages of fevers, such as typhoid and scarlatina, the higher functions of the mind are often suspended, either from exhaustion, or because the cortical centres have been disturbed by the severity of the febrile action. In these grave physical conditions the automatic and purposeless repetition of words and muscular movements becomes quite noticeable. Subsultus tendinum, carphologia, tiresome utterance of some particular sound or word, indicate that the higher cerebral functions have been suspended, and that the lower centres are acting at random and without the direction of the former. In this case the prognosis is grave because the vital forces themselves are waning and volitional activity is suspended through exhaustion of the cortical centres.

In chronic insanity the prognosis as to mental recovery of the patient may be equally grave, for the reason that healthy functional activity of the cortex has been permanently disturbed by the disease, which, though not necessarily fatal to life, is most assuredly so to mental restoration.

For the reasons just outlined the chronic insane are very likely to develop objectionable habits. The study of the physiological origin of many of the habits of this class of the insane would be most interesting and instructive. Two laws underlie every form of nervous activity, and furnish a physiological reason for the constant tendency toward automatic and habit-action exhibited by the chronic insane in whom inhibitory impairment always exists. 1. The discharge of the nerve-centres occurs along those tracts which offer the least resistance. 2. The more frequently the discharge occurs along a given line, and the weaker the inhibitory resistance, the easier does a repetition of the discharge become, and the more certain its permanent automatic establishment.

If, for any reason, in those conditions of mental disease characterized by a weakening of the will-power, one especial route is established either by reason of delusion, or mere fortuitous circumstance, the probability is that this particular route will continue to be the one most frequently traversed by nervous force in its passage from the brain to the periphery. A delusion, an hallucination of sight or hearing, some peculiar condition in the patient's environment may have first initiated certain actions which, by being unresisted, and hence repeated, lead to the establishment of a habit. Probably in some such simple and purely fortuitous way are developed the pulling out of the hair, tearing the clothing, walking in a beaten path, making singular motions or uttering meaningless sounds—in fact any of the countless strange habits of the insane. It matters little whether the performance of these habits is painful or disagreeable, no other alternative seems open to the patient when, through weakness of will and intelligence, the morbid route has once been established. Some morbid sensation in the scalp or chin to act as an exciter, or merely the absence of anything of an intelligent character to engage the attention, may lead to the plucking out of the hair or beard, which impulse, meeting with no resistance, soon develops into a persistent habit. A delusion about the bed may lead the patient into the habit of standing up all night, and if not interrupted, nothing short of restraint will prevent exhaustion, so persistent will the impulse become to remain on the feet.

The importance of the early breaking up of bad habits among the insane will be readily understood. Fortunately the same tendency to automaticity of action may be utilized in a good as well as a bad direction. By careful supervision we may succeed in breaking up many useless and vicious habits by supplying some simple mechanical occupation for the hands, thereby utilizing the automatic nerve-activity characteristic of the disease. And in doing this we may even seem to retard mental deterioration. Judiciously selected, mechanical employment among the insane has become therefore a valuable means of treatment.

It is quite obvious that photographic illustration of the entire subject of automatic nerve-activity is impossible,

and yet enough in this direction may be shown to demonstrate the important part played by morbid automatic cell-activity in the physical expression of chronic insanity, and, to a certain extent, in some forms of acute alienation. It is evident that illustration of this part of the subject must be limited to postures. The significance of postures in health has been referred to by Dr. Francis Warner in an article on "Muscular Movements in Man," in the April number, 1889, of the *Journal of Mental Science*. He says: "Postures depend upon the ratios of nerve-muscular action, and to some extent they indicate the present ratios of static efferent force proceeding from the centres concerned. Observations show that the postures, when not due to a present stimulus, or when produced by a weak stimulus from without, such as a sound or sight, correspond to and are signs of the general condition of the central nerve-system."

The postures maintained, oftentimes for long periods, by the insane possess a special interest because they are a pretty sure index of the morbid condition of the central organ of innervation.

Cases LI., LVIII., and LX., illustrate peculiar and somewhat painful attitudes which were taken by patients suffering from secondary or terminal dementia. And in Case LXV. is seen a singular position maintained by a patient in a condition of stuporous melancholia. In these

Fig. 341.—Case LXV. Melancholia with Stupor. Showing persistent morbid attitude maintained for hours. (From photograph taken by author.)

and similar cases the intensely interesting question is always suggested, how came such peculiar habits to be initiated? The wards for demented patients will present numerous cases of this character which will afford material for physiological and psychological study. The careful investigation into the early development of mechanical movements, attitudes, and meaningless habits among this class of patients, would amply repay the time and labor expended in this direction, and throw some

Fig. 342.—Case LVIII. Chronic Dementia. Peculiar and uncomfortable attitude maintained daily for years. Automatic nerve-muscular activity. (From photograph taken by author.)

light on the processes of cerebration and their connection with muscular movements.

The singular postures shown in the photographs of Cases LI., LVIII., and LX., were gradually assumed by the patients while under the writer's care, and yet so very slowly were they initiated that they became fixed and habitual positions before any especial attention was called to the fact. In this way the real causes that led up to the final establishment of the habitual posture were lost sight of. From what was known of the patients, the impression would be readily formed that in Cases LVIII. and LX. delusions of suspicion or a dislike to seeing persons about, led to a habit of hiding the face, as is often witnessed among bashful and diffident children. As these particular patients became more demented, a position which was at first assumed as the result of an active delusion finally developed into a permanent habit, simply because nervous force, flowing along this route from centre to periphery for so long a time in obedience to impulses derived from morbid ideas, and meeting with little inhibition, continued to take this route long after active thinking had ceased.

Another interesting fact concerning these strange attitudes assumed by these patients is, that they seem utterly oblivious to the discomfort and even the painfulness of these constrained positions. Cases LI. and LX. would maintain the posture for hours; and Case LVIII., from

Fig. 343.—Case LI. Chronic Dementia. Showing peculiar and uncomfortable attitude assumed by demented person as a result of morbid and persistent nerve-muscular activity. (From photograph taken by author.)

the hour of rising until bed-time, was continually in the attitude shown in the photograph. The muscles concerned in the maintenance of these postures were in a high state of tension, showing that a certain amount of "static efferent force" was being transmitted continuously from the centres within the sensorium to the periphery over these morbidly pre-established routes. Nearly all the other healthy activities of mind seemed in these cases to have ceased with the exception of the mere processes of organic life, and the entire energy of the sensorium was expended in keeping up these automatic and useless positions. Any attempt to move the arms into a more easy position was met by firm resistance, which was not spasmodic but persistent in character. That these attitudes would be painful to a person in health, anyone can demonstrate by attempting to maintain similar positions for even a few minutes at a time.

There remain for consideration the various positions and expressions of the eye as modified by insanity. These, though largely dependent upon the different pathological conditions already discussed, still are deserving of separate mention.

Every writer upon physiognomy gives great prominence to the eye as an agent in expression. Bell, in his "Anatomy of Expression," has said: "The eye is the most lively feature in the countenance; the first of our senses to awake, and the last to cease motion. It is indicative of the higher and holier emotions, of all those feelings which distinguish man from the brutes" (Ibid., p. 94).

Schack, with earnest enthusiasm, says: "The eye is the most immediate and most delicate point of transition between body and soul; it is the most interesting and most *spirituelle* part of the physiognomy, and has been rightly called the mirror of the mind. Brilliant or dull, it contains remembrances of the past and enables us to prophesy of the future. Joy gives it clearness, sadness and grief fill it with shadow; it speaks a language which sympathy understands at once without the aid of words or a dictionary" ("The Physiognomy in Man and Animals," p. 76).

In speaking of the expression of the eye physiognomists generally allude to the eyebrows, the eyelids, and those parts immediately surrounding the organ as well as the eyeball itself. Indeed, it would be difficult to do otherwise, so intimately associated are the muscular movements of these various parts, and so actively do they all enter into what is commonly called the expression of the eye. Schack, in an interesting chapter on the eye, gives several pictorial illustrations which are intended to represent that organ in the various states of joy, anger, revenge, shame, and so forth. In these sketches it is noticeable, however, that the expression owes its individuality, in nearly every instance, to the position of the

Fig. 344.—Case LX. Chronic Dementia. Uncomfortable attitude maintained for a long period. Automatic nerve-muscular activity. (From photograph taken by author.)

parts about the eye as much as to any particular change in the organ itself.

In a limited way, however, the eye itself entirely dissociated from surrounding parts, is subject to certain

changes which modify its expression. In studying the eyes of the insane it is proposed to limit our observation to these very changes, the muscular movements of adjacent parts having already received discussion in previous sections.

Three conditions modify the expression of the eye:

I. The state of the iris.

II. The degree of brilliancy of the organ.

III. The position of the eyeball in its socket and its mobility.

I. The state of the iris may be either one of contraction or dilatation. Neither of these, however, plays any prominent part in modifying the expression of the individual.

II. The degree of brilliancy of the organ exerts a wider influence upon expression, and variations from extreme dulness to remarkable lustre are of frequent occurrence in the different phases of insanity. This quality of brilliancy is quite characteristic of the eye in states of health, and has been alluded to by Darwin, Mantegazza, Schack, and others. Its physiological causation is of much interest and has been variouly explained by different authors. Darwin says: "A bright and sparkling eye is as characteristic of a placid or amused state of mind, as is the retraction of the corners of the mouth and upper lip with the wrinkles thus produced. Even the eyes of microcephalous idiots, who are so degraded that they never learn to speak, brighten slightly when they are pleased. Under extreme laughter the eyes are too much suffused with tears to sparkle; but the moisture squeezed out of the glands during moderate laughter or smiling may aid in giving them lustre; though this must be of altogether subordinate importance, as they become dull from grief, though they are then often moist. Their brightness seems to be chiefly due to their tenseness, owing to the contraction of the orbicular muscles and to the pressure of the raised cheeks. But according to Dr. Piderit, who has discussed this point more fully than any other writer, the tenseness may be largely attributed to the eyeballs becoming filled with blood and other fluids, from the acceleration of the circulation consequent on excitement of pleasure. He remarks on the contrast in the appearance of the eyes of a hectic patient with a rapid circulation, and of a man suffering from cholera with almost all the fluids of his body drained from him. Any cause which lowers the circulation deadens the eye. I remember seeing a man utterly prostrated by prolonged and severe exertion during a very hot day, and a bystander compared his eyes to those of a boiled codfish" (Darwin, "Expression of the Emotions in Man and Animals," Am. Ed., p. 206).

Schack, in describing the physiognomy of laughter, says: "The glance of the eye at the same time becomes shining and brilliant, a fact which is in part due to the increased secretion of the lachrymal gland, and probably also to the inner tension of the eyeball which is the result of the increase of circulation under the influence of pleasure" (Schack, ibid., p. 126).

Mantegazza says with great truth: "The eyes have a remarkable brilliancy which goes far toward modifying the expression. The eye of one who laughs, of one who thinks or speaks with energy, is very brilliant; the eye of a stupid, feeble, or sick man has little brilliancy; while the eye of one who is moribund seems to be almost extinguished. This brilliancy deserves an attentive examination, for it is one of the most important and obscure elements that enter into the study of the eye. For the moment we ought to content ourselves with saying that this condition depends in part upon the structure of the cornea, upon its variable convexity under the influence of the ocular muscles, upon the humors secreted by the eye, and especially upon the veil of tears which bathes its entire outer surface" (Mantegazza, ibid., p. 36). And again the same author says: "Popular opinion attributes a lively eye to the man of genius, and a dull eye to the stupid man. In fact, in the former a continuous discharge of nerve-energy is being liberated from the central nervous system which finds an abundant outlet in the numerous muscles of the eye; hence the movements and oscillations of these muscles, hence also the veil of tears which renders the eye brilliant" (Mantegazza, ibid., p. 245).

These different physiological reasons for varying brilliancy of the eye under corresponding emotional and intellectual states, find interesting illustration and confirmation in the eyes of the insane. Among the insane, as in no other class, there exist in full force the very conditions noted by the physiognomists whose views have just been quoted. Prominent among the factors that enter into the causation of a brilliant eye, none are more important than the varying tenseness of the ocular muscles, due, as Mantegazza says, to the continuous discharge of nerve-energy along the efferent routes to these particular muscles. Varying degrees of convexity of the eyeball, caused by the alternate contraction and relaxation of the ocular muscles, produce variations in the refraction of light from its smooth surfaces, a fact which may in large measure account for the changes in brilliancy, assisted as it must be by the squeezing out of a greater or less amount of fluid from the lachrymal glands.

These different degrees of muscle tension, varying as they do from the ordinary tonicity of health to extreme contraction and relaxation, are, as has been seen, of common occurrence in the different types and stages of mental disease. Variations in the brilliancy of the eye among the insane would seem, therefore, to find one very natural explanation in the different degrees of efferent nerve-muscular activity, so commonly witnessed in this disease, and which is distributed to the ocular in common with all other muscles, causing thereby varying degrees of tension and convexity of the eyeball, and corresponding variations in the refraction of light from its surface.

Another cause assigned for increased brilliancy of the eye is that given by Piderit, and referred to by Darwin in the quotation given above, namely, an acceleration of the circulation consequent upon emotional excitement. Nearly all conditions of increased cerebral circulation are followed by a peculiar brilliancy of the eye. On the contrary, a slow and depressed circulation is followed by a dull and lustreless eye. Even in conditions of depraved physical health, provided the circulation is more rapid, the eye assumes a brighter aspect. We see this in the later stages of phthisis, where, as a compensation for the loss of aerating surface within the lung, the heart is urged on to greater frequency and impels the blood more rapidly through the arteries; and by reason of this heightened circulation, the eyes of such patients assume oftentimes an almost unnatural brilliancy. By reason of increased cerebral circulation it may also be quite likely that the eye of acute mania assumes its brilliancy, while in the slow circulation of melancholia and dementia just the reverse obtains.

We may conclude, then, that changes in the brilliancy of the eye may be due to either one or both of the two causes mentioned: varying tension of the eyeball caused by the transmission of nerve-muscular force from the nervous centres to the ocular muscles, or the presence of a greater or less amount of fluid within the transparent media of the eye as a result of increased flow of blood in that region. Either or both of these causes may account for variations in brilliancy noticeable in different forms of mental disease.

Unfortunately, this important element in the expression of the insane does not admit of satisfactory illustration, the flash of light from the eye being of too fleeting and evanescent a character to be caught and retained by the sensitive plate in the camera. In a general way, every form of insanity which is attended by increased nervous activity, with or without more rapid heart-action, is characterized by brilliancy of the eye. The eye of dementia, of melancholia, of the depressed stage of *folie circulaire*, is dull and lacking in brilliancy; the eye of acute mania, of the exhilarated stage of *folie circulaire*, and of those acutely maniacal conditions frequently witnessed in paresis, is brilliant and glistening.

Striking illustrations of a change from brilliancy to dulness are often very noticeable in different stages of the disease in the same individual, although it is ex-

tremely difficult to get a satisfactory portrait illustrating such change.

III. The position of the eyeball in its orbit, and its mobility. The position of the eyeball in the orbit is a very prominent factor in facial expression. Six small muscles guide the eye in various directions. Four of these muscles, the *recti*, are under the influence of the will, and during our waking hours are in almost constant activity. They conjointly balance each other and maintain that slight convergence of the eyes which Darwin says is necessary in binocular vision. The two oblique muscles are involuntary in character and apparently serve a double purpose. They rotate the eyeball on its antero-posterior axis—"this kind of movement being required," as Gray says, "for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye." The oblique muscles also serve the purpose of rolling the eyeball upward under the lid. The recti being voluntary muscles, their action ceases during sleep and in states of deep unconsciousness, and then the oblique muscles, meeting with no counteracting influences, roll the eyeball upward. Sir Charles Bell called attention to this interesting action of the oblique muscles, which is undoubtedly intended to protect the delicate surface of the cornea from being exposed, in case the lids remained partially opened during states of unconsciousness.

Between the extreme condition of entire relaxation, occurring in states of sleep and unconsciousness, and the varying degrees of tension necessary to the direction of the eyes during the waking hours, the recti undergo a certain relaxation corresponding to the state of the faculty of attention.

In health the faculty of attention is in nearly continuous activity. During the waking hours some person or some thing near or remote is, by this act of attention, being made an object of vision. Except in moments of introspection or reverie the sensorium is, by the guidance of the attention, being brought in contact with the environment through the sense of sight. For this reason the eyes are kept in a state of gentle convergence—such a position being necessary to binocular vision. The least withdrawal of the attention from any object in the immediate or remote environment is at once followed by a partial relaxation of the recti muscles, and as a result the eyes slightly depart from their condition of convergence and appear to be directed forward, or in nearly parallel or slightly divergent lines. This is the position of the eyes in states of reflection or absent-mindedness, which gives to the face a characteristic expression that receives a familiar and sometimes annoying illustration in every-day conversation. While conversing with a friend we are suddenly made aware, by a change in the position of his eyes, that he is not any longer looking at us, but apparently through or beyond us; and by this same parallelism of the eyes we are conscious that his attention has ceased to be interested in what we are saying and has become occupied with other things.

As before remarked, impairment of this faculty of attention is one of the first results of insanity. Disordered inhibition associated with enfeeblement of the will-power leads to a positive weakening of the faculty. The mind of the insane patient is often entirely preoccupied. Morbid trains of thought, delusions of suspicion, fears, intense subjective ideation fill his mind, and, by reason of the inhibitory incapacity consequent upon the disease, these morbid psychic processes continue unchecked. As a result the recti muscles undergo relaxation, allowing the eyes to depart from that state of convergence which is the usual result of the normal exercise of the faculty of attention.

Ocular parallelism or divergence, therefore, which follows absent-mindedness in health and is then of mere temporary character, may become in many forms of insanity a prevailing condition, thereby forming a very striking feature in the facial expression of the disease. In such a condition of the eyes the person does not seem to take any interest in his environment. Oftentimes the eyes have a staring look, and in many forms of insanity all attempts at diversion are futile, the patient continuing to manifest that painfully stony and glaring aspect which show how intense is the mental absorption. Indeed, one of the first symptoms of insanity observed by the friends is this peculiar expression due to ocular parallelism. They often refer to a certain strange, unnatural, or wild appearance about the eyes which is undoubtedly brought about by the divergence due to almost constant morbid preoccupation of the attention.

In the late John McCullough's masterly representation of the insanity of Virginius, or the feigned insanity of Brutus, one of the most striking features of his portrayal of the morbid mental condition was the apparent centring of the eyes upon vacant space, rather than upon near objects. The idea was at once conveyed to the

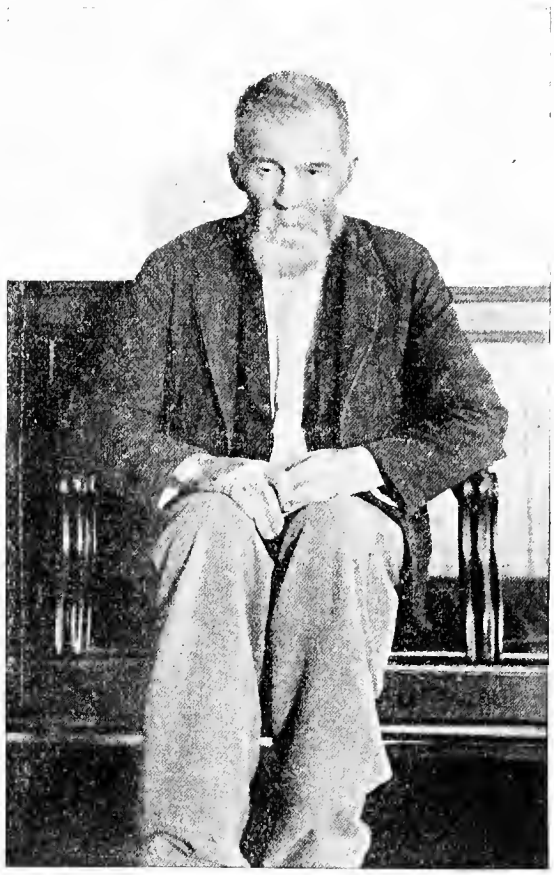

FIG. 345.—Case XLIX. Senile Dementia. Showing ocular divergence, neglect of personal appearance, general absence of healthy muscular tonicity. (From photograph taken by author.)

spectator that the mind of the character represented was preoccupied with ideas entirely outside his environment.

In the early stages of delusional insanity, in melancholia, in many conditions of mania, and in dementia, ocular parallelism is of frequent occurrence, either on account of the intense preoccupation of the mind with subjective ideas, or on account of absence of ideation, or, lastly, because ideas are so hurriedly brought up before the mind that the individual is unable to direct his attention upon anything or anybody about him, and convergence, if it does occur, is merely momentary. In conclusion, it may be said that ocular parallelism or convergence among the insane represents, if persistent, the extent to which the faculty of attention is weakened by the disease. Thus the demented, in whom the power of attention has been almost entirely destroyed, nearly always presents a

vacant, staring appearance of the eyes, and in extreme cases it becomes absolutely impossible to induce that convergence of the eyes characteristic of the healthy binocular vision. The same is true of cases afflicted with *melancholia attonita*. From the extreme and persistent ocular parallelism noticeable in terminal and organic dementia and *melancholia attonita* there may occur all

FIG. 346. Case XXXIII. Acute Suicidal Melancholia. A. Taken at height of attack. Trophic alterations, ocular divergence, and self-absorption well marked. (From photograph taken by author.)

varieties of the condition to those cases in which the faculty of attention is so slightly disturbed by the mental disease that the position of the eyes does not vary from that which is characteristic of health.

Case XLIX. illustrates the fact that deficient ideation, accompanied with actual impairment of the faculty of attention, is attended with parallelism of the eyes or slight divergence. If one should stand directly in front of this individual he would find it almost impossible to place himself directly in the line of his vision. This patient's position is very characteristic. He appears to be staring into vacancy, not because his mind is preoccupied with any particular line of thought, but rather on account of absence of active thought of any kind.

Cases XXXI. (see page 510) and XXXIII. (see page 528) present ocular divergence in states of active melancholia. In these individuals the eyes depart from the normal convergence of health because the mind is so intensely preoccupied with some one dominant idea or class of ideas as to be actually incapable of being aroused or attracted. It is impossible to interest these unhappy minds in any subject. Either some one idea of painful character has excluded every other thought, or the cortical centres themselves have been so overwhelmed by the force and intensity of the morbid ideation as to be incapable of farther functional activity. These same cases are particularly interesting because in each of them we have excellent views both at the time of greatest morbid intensity and during perfect health.

In XXXIII. the series show the gradual but steady progress of the mind toward recovery. In Fig. 346, A the eyes are fixed in a state of divergence. No amount of urging can prevail upon the person to awaken from his intense painful preoccupation of mind. In Fig. 347, B there is evidently the beginning of an awakening—the attention can be aroused momentarily. In Fig. 348, C and Fig. 349, D the change has become complete and the patient takes an intelligent interest in his environment. This case recovered and retained perfect recollection of the fearful mental torture through which he passed. He was able to give an intelligent account of his ideas, and the reason for his vacant, preoccupied, divergent stare lay in the entire suspension of the faculty of attention to anything but his own morbid ideas, and a complete lack of interest in anything in his environment.

Case XLII. (see page 519) shows ocular divergence in a state of acute mania. Here the cerebral activity is so persistent that ideas are hurried through the mind more rapidly than they can be grasped by the attention. The condition is exactly the reverse of what occurs in dementia. In dementia there is absence of ideas, while in mania there is such an excess of ideas that the attention is bewildered and paralyzed. So great is the mental confusion that the patient is incapacitated from taking any interest in his environment. The eyes of such patients are rarely centred upon anything, and complete incoherence of thought is manifested by the position of the eyes almost as much as by disordered speech and action.

Cases of mild mania and delusional insanity very frequently present this condition of ocular divergence. Either the mind is confused with a number of irrelevant ideas and the attention is thus diverted, or some one persistent idea or series of ideas so completely absorbs the patient's attention that that faculty seems to be incapable of being aroused by anything in the immediate environment.

The mobility of the eye in the orbit is quite a prominent factor in facial expression, and is subject to great variation in the different phases of insanity. The nervous supply to the muscles of the eye is abundant and is

FIG. 347.—Case XXXIII. B. Taken three months later. Self-absorption less marked. Delusions beginning to weaken. Health improving. (From photograph taken by author.)

distributed through three main tracts: the motor oculi, the fourth nerve, and the sixth, or *abducens*. The discharge of nervous energy which is constantly taking place along the various efferent tracts during periods of cerebral activity, undoubtedly follows these three nerve-tracts to the muscles of the eye. Such an elimination of nerve-force is, as we have already noticed, one cause of the brilliant and glistening eye of mental activity. In

the active cerebral excitement consequent on attacks of mania a similar discharge of nervous energy passes along these same routes to the various eye-muscles. Not only are the eyes of the actively insane quite brilliant, they

Fig. 348.—Case XXXIII. C, taken two months after B. Convalescence established. Healthy ideation and restoration of physical health. (From photograph taken by author.)

also possess great mobility; and rapid movements of the eye, giving to that organ a character of restlessness, are important factors in the facial expression of nearly every case of active insanity.

This pathological transmission of nerve-force from the

Fig. 349.—Case XXXIII. D. Recovery. Taken at time of discharge. (From photograph taken by author.)

cerebral centres to the muscular periphery, which has been referred to in the previous pages as excessive, deficient, or automatic in character, leads to a certain asymmetry of the muscles, particularly noticeable in the face. For this reason any collection of photographs of the insane presents a bizarre appearance. In acute mania, for instance, irregular and spasmodic action of the cortical centres produces meaningless expressions and asymmetrical contractions of the facial muscles, noticeable in Case XLII, Fig. 337, A (see page 519). Here it may be supposed that the centres in the motor area act independently of each other, or that there is imperfect co-ordination. One group of muscles are contracted, while the corresponding group upon the other side are relaxed. The usual bilateral contractions that occur in the normal facial expression of the emotions are absent in these cases (see Fig. 350).

Among the demented insane organic degeneration of cortical areas produces a very similar result. This is illustrated in the strange attitudes and persistent meaningless position of groups of muscles. In dementia it may be supposed that one group of cortical cells may have been destroyed by degenerative processes, and that co-ordinate action between cortical areas ordinarily associated has thus become physically impossible. Again, in acute alcoholism the same kind of irregular and one-sided action of muscles occurs. And in this case there is good reason for supposing that the toxic influence of the drug has impaired the normal activity of the cell to such a degree that there is a withdrawal of the supply of nerve-force necessary to healthy muscular action. The alcohol in the cerebral circulation affects one group of cells more than another, or so impairs normal co-ordination that muscular movements are jerky and uncertain. Both the face and the gait of the intoxicated man disclose the asymmetrical and irregular action of the centres of the motor area. In the paretic, the organic changes that have occurred in the cortical cells are clearly revealed in the imperfect co-ordination of different groups of muscles, particularly those of the mouth, tongue, and throat.

Fig. 350.—One-sided Contraction of the Facial Muscles of Expression. (From Kirchoff's Handbook.)

In studying the physical expression of insanity, one thing is worthy of note. Departure from normal expression keeps pace with functional and organic disturbance in the cortex. The distortion and agitation of mania, the dissolution of expression witnessed in organic dementia, or in melancholia with stupor, correspond to extreme functional or structural disturbance in the cortical centres. As inhibition, the power of attention, and intellectual activity depend upon the integrity of the cells in the cortical area, we may conclude that the changes in the physical expression of the insane are associated with certain inhibitory and intellectual disturbances, accompanied in the later stages with motor enfeeblement. These psychological concomitants of the physical expression of insanity represent the pathological changes that have occurred in the cortex. Hence it happens that the expression differs in different cases of mental disease according to the degree of functional or structural impairment of the cortical area. Slight departure from normal expression is evident in Cases XII. (see page 515)

and LIV. (see page 521), notwithstanding that the patients are affected with marked delusional insanity; on the other hand, in Cases XLII. A (see page 519), LXV. (see page 524), XXXIX. (see page 518), and in the woman shown in Fig. 351, there is great disturbance, and even distortion of expression in some instances. The explanation of the difference in the character of the expression in the two classes of cases may be found in the varying character of the functional disturbance in the cerebrum. In Cases XLII. A, LXV., etc., normal intellectual activity is interfered with, inhibition is diminished, and the power of attention so temporarily or permanently damaged as to be nearly useless; while in Cases XII. and LIV. the inhibitory and intellectual processes are quite well preserved, notwithstanding the fact that there is marked delusional insanity. Case XII. could sit for his photograph with as much ease and confidence as any sane person, owing to the preservation of inhibitory power and the ability to concentrate his attention upon his immediate environment. Case XLII., on the other hand, owing to his motor restlessness and his intellectual incoherence, was entirely unable to sit intelligently for his portrait, and a likeness was only secured by the aid of instantaneous photography. The greatest diversity of physical expression is encountered, therefore, among the insane. Many very natural and intelligent countenances are noticeable in the extremely deluded, simply because the functional cortical activities underlying inhibition, attention, and ordinary intellection have not been impaired.

Fig. 351.—Delusional Melancholia, with Ideas of Fear. (From Kirchoff's Handbook.)

Fig. 352.—Delusional Melancholia, with Ideas of Fear. (From Kirchoff's Handbook.)

In conclusion, it may be said that the study of the physical expression of the insane by the aid of instantaneous photography is a matter of much interest to the psychologist, indeed may become a valuable aid to diagnosis and prognosis. A series of photographs illustrating an individual in different stages of mental alienation gives a good illustration of changes that have taken place in the central nervous system. Every hospital for the insane should possess a photographic outfit and preserve pictures illustrating the individual in various stages of his disease. The slow but steady disintegration of expression preserved in the photograph will become an accurate index of the organic failure that has occurred in the brain. On the other hand, the return of normal muscular tonicity, of natural expression as evidenced in the trophic condition and normal motor activities of the muscles of the face and extremities, is an equally sure index of the reparative processes that have occurred in the central nervous system. It may not be too visionary to suppose that a careful study of photographs, taken at different periods in the life of an individual whose case has come before the courts, may prove to be of medico-legal importance, and give the medical expert valuable assistance in comparing the past with the present meutal and moral status of the case. *Charles P. Bancroft.*

INTESTINAL DISEASES: DYSENTERY. In the light of recent investigation the word "Dysentery" has but little right to occupy a place at the head of this article. Originally used to express a certain set of symptoms, which differed entirely from those included under the term "Diarrhœa," it uow covers pathological states which differ very much in nature and extent, and does not define varieties which are unlike anatomically and etiologically. The so-called dysenteric lesions may have diarrhœa as a symptom, and simple catarrhal changes in the mucous membrane may be attended by tormina, tenesmus, and dysenteric stools.

The symptoms vary to such an extent that they cannot be made a basis for study; pathological changes and etiology will alone help us to define the nature of the different forms, and a new nomenclature must be based upon new methods of investigation.

Nevertheless the word dysentery is still used to indicate certain pathological changes which occur in the intestine from various causes; it even includes a condition proven to be due to a specific cause with characteristic anatomical changes, as well as other special ulcerative changes which may be dependent upon bacilli not yet isolated.

In the present state of our knowledge the conditions formerly included under our term "Dysentery" can be differentiated into—*a*, simple catarrhal dysentery; *b*, diphtheritic dysentery; *c*, amœbic dysentery.

Catarrhal Dysentery.—In the milder cases of this form there may be no change beyond a more or less intense hyperæmia of the mucous membrane occupying areas of varying extent. Punctiform hemorrhages may be seen in the mucosa or submucosa. The mucous coat may be swollen and covered with much mucus and pus cells. The surface epithelium may be absent, and the exfoliation of epithelium may involve the glands. There may be destruction of the tissue of the mucous membrane; shallow ulcers are seen, and are formed by extension of the superficial softening. Sometimes the ulcers extend to the muscular coat. In the submucosa, which is much thickened, there are masses of granulation and pus cells, and the connective-tissue cells are enormously swollen. The solitary follicles are swollen from hyperplasia of lymphatic tissue; from distention they burst and an ulcer is formed. This form may undergo cure by an arrest of the disease and healing of the spots of ulceration, or the ulcers remain and show no tendency to heal.

This form is frequently a complication of other and generally chronic diseases. It constitutes the most frequent form outside of the tropics, and is the one which we most frequently see as sporadic dysentery.

The *symptoms* usually begin suddenly, sometimes with diarrhœal discharges, or with "dysenteric" stools from the start. These consist of blood and mucus; later, pus may be seen and the discharges may become more fluid and abundant. Tormina, rectal tenesmus, vesical tenesmus, prolapsus ani, with continued fever, constitute the chief symptoms. Improvement begins with a diminution in the number of the stools, the disappearance of blood and mucus, and the reappearance of

fecal matter. The fever subsides and there is a return of appetite and strength. Relapses may occur. The duration is from one to two weeks in mild cases, but the attack may be prolonged to four weeks.

Diphtheritic Dysentery. — Diphtheritic dysentery is so called because of the presence of a membrane on the surface of the mucous membrane of the large intestine, and sometimes of the small intestine as well. This is composed partly of a fibrinous exudation, but is chiefly necrotic tissue.

The process is as follows: On the surface of the hyperæmic mucous membrane small, whitish-gray patches appear, which cannot be removed without causing a loss of substance. By coalescence large membranous areas are formed, which may completely line portions of the tubes, or the patches may continue distinct, small membranous patches being scattered over the surface. These changes are most marked at the bends of the intestine. The intervening mucous membrane may be intensely hyperæmic in the most acute cases; in others it is unchanged.

Microscopic examination shows the membrane to be composed of necrotic cells, nuclear detritus, and masses of fibrine, which involve the mucosa to varying depths. Between it and the healthy tissue there is a line of demarcation formed of pus cells. In the submucous tissue there is intense injection. The vessels are dilated and surrounded by a zone of small-cell infiltration. Fibrine is sometimes exuded in the submucous tissue, having no connection with the surface membrane. The pseudomembrane is subsequently separated from the tissue below by suppuration, and is thrown off, leaving an ulcerated surface. The ulcers vary in size with the extent and depth of the necrosed tissue; they may heal, or exudation and necrosis may go on, destroying deeper and larger areas and causing large and irregular ulcers. By healing, large and irregular cicatrices may form, and the wall of the intestine may be thickened and its lumen narrowed. Inflammation may extend to the peritoneum or perforation may result.

This form of dysentery is the one usually found in epidemics. The *symptoms* are more pronounced, and constitutional disturbance is more marked than in the preceding form. Fever of varying intensity is observed, with great prostration, abdominal pain, and frequent discharges. The stools at first may present the same characters as those in the catarrhal form, but later they become more watery, with membranous fragments, and at times large necrotic masses of putrid odor are passed, with or without tenesmus, depending upon the location of the ulceration.

The bacteriological research in both catarrhal and diphtheritic dysentery is full of interest, though nothing positive can be stated as to any specific bacillus. In 1869 Hallier observed a number of micrococci in dysenteric discharges, which he claimed to have differentiated from the discharges of diarrhœa and healthy fæces.

There are two species of bacteria present in the healthy intestine, viz., *bacterium lactis aërogeneus*, which is usually found in the upper, and *bacterium coli commune*, found normally in the lower intestine. Councilman suggests that the part the *bacterium coli commune* plays in dysentery may be an important one. It is pathogenic in a number of the lower animals, and if the normal resistance of the tissues of the intestine is lessened from any of many causes, it may act in man as a pathogenic germ. It is found not only in the ulcerations, but it is also found to have penetrated the tissues.

Booker, in a series of careful examinations upon a child which had died of dysentery, claims to have isolated a germ not found in the normal intestine or in diarrhœal discharges. It resembles in morphology the *bacterium lactis aërogeneus*, but is smaller, and differs from it by producing fermentation in milk. The new bacterium was found in large quantities in the diseased part of the intestine, and was absent in the healthy part.

In 1876 Normand, having made a microscopic examination of the stools of soldiers returned from China with severe dysentery, discovered a parasite which he named "*bacillus stercoralis.*" It is a fusiform germ of the nematode family, and very similar in appearance and size to the filaria of the human blood. This germ measured about one millimetre in length, and was thirty to forty micro-millimetres broad, a little pointed in front and tapering to a point in the back. Normand, having first proven the constant presence of the germ in nearly all the cases of severe dysentery, did not hesitate to call it the specific agent of the disease; but this idea was soon abandoned.

Amœbic Dysentery.—The intestine is always considerably thickened, the submucous coat being considerably affected, though the other coats are involved to varying extents. This thickening is due not only to the œdematous condition, but there are sharply circumscribed projecting nodules, in which are small cavities filled with a viscid gelatinous pus. The mucous membrane covering these cavities becomes necrosed and sloughs off, leaving irregular ulcers, which may connect with others by a sinuous tract, burrowed under apparently healthy mucous membrane.

The submucous coat is generally infiltrated and œdematous; it softens, and by necrosis of overhanging tissue ulcers, with undermined and ragged edges, are formed, which have the muscular coat for their base. The cellular infiltration extends through the upper layers of necrosed muscular tissue into the septa of the intermuscular connective tissue and into the submucous coat.

Destructive necrosis goes on in the tissues of the circular muscular coat, and masses of it slough off and are passed by stool. The next step is great thickening of the adjacent peritoneum, which next becomes the seat of disintegration; adhesions form with neighboring viscera and with contiguous links of intestine.

The mucous membrane at a distance from the seat of the acute process is not altered; lower down, some of the glands are dilated and filled with mucus and pus cells, the epithelial cells are distended with mucus, and the epithelium everywhere contains an increased amount of mucus. By confluence of neighboring glands cysts are formed. Near the ulcers the glandular epithelium proliferates with bud-like projections into the tissue below.

Lambl first saw amœbæ in the intestinal contents in 1849. In 1875 Lösch, in examining microscopically the stools of a patient, twenty-four years of age, who was suffering with an ulcerative affection of the large intestine, discovered amœbæ in great numbers, which he called "amibe du colon," or amœba coli. Next, he injected these stools into the intestines of four dogs, one of which had vomiting and diarrhœa. The animals were then killed, the intestines were found to be inflamed, were covered with bloody mucus, and showed many ulcerations. The amœbæ were found in the mucous membrane and in the ulcers. The parasite appeared as a protoplasmic mass and measured on an average twenty to fifty μ; in motion and with their greatest elongation they reached over sixty μ. Their protoplasm is very granular and encloses six or eight round vacuoles.

Koch, in 1883, found the amœba in the intestines of those dying from dysentery. Kartulis attempted to prove that the amœbæ played the principal *rôle* in the pathogenesis of dysentery. He also found them in other ulcerative affections of the intestine, viz., typhoid fever and tuberculosis. In certain complications of dysentery, and especially in abscess of the liver, Kartulis found the amœbæ in the pus, associated nearly always with the ordinary microbes of suppuration. He did not believe that the parasite was pyogenic in itself, but that it only prepared the way for the microbes of suppuration. Osler, first in America, reported a case of abscess of the liver in the course of dysentery, in which he found the amœbæ in large numbers. Much that we know of this form of dysentery is due to the work done in Johns Hopkins Hospital by Osler, Councilman, and Lafleur, and we are indebted chiefly to the paper of Councilman ("Transactions of the American Association of Physicians, 1892") for our knowledge of the pathological anatomy of amœbic dysentery. Dock afterward demonstrated the amœbæ in a case of dysentery contracted in Texas. Vassi

has since found them in a case of abscess of liver; he found only a small number in the pus, but they were present in great numbers on the side of the abscess, also in some of the small branches of the portal vein.

The constancy of the presence of the amœba in the various manifestations of dysentery adds weight to their probable pathogenic influence. Massiutin has found these same parasites, with characters absolutely identical with those described by Kartulis, in other affections than dysentery (chronic intestinal catarrh, mucous diarrhœa, and acute enteritis), and on the strength of his researches he repudiates the idea held by Kartulis as to the specificity of the amœba as the parasite of that disease. In the meanwhile Kartulis is still experimenting, and his researches rather confirm his idea, though the results are not sufficiently proven to be assured. He has been able to produce a mucous and bloody diarrhœa by injecting the amœba cultures into the rectum of a cat.

The amœbæ are found in the submucous tissue around the ulcers; apparently they themselves produce few lesions in the mucous membrane, but they first attack the submucosa and the mucous membrane is affected from below.

They are also found in the lymphatics and sometimes in the blood-vessels. The tissues in which they are seen are infiltrated with cells. There is no necrosis, and the neighboring connective-tissue cells sometimes lose their nuclei and the nuclei split. Most numerous in the smallest ulcers, when the process is most rapid and where there is no suppuration, they are scattered through the tissue or lead the advance of cell infiltration.

Abscess of the liver was found in six out of eight autopsies of amœbic dysentery (Councilman); in four cases, there was more than one abscess, and in two cases they were very numerous and small; in every case the right lobe was the seat of this change, and in two cases there were abscesses in the left lobe. In the smaller abscesses there was a small amount of glairy, semi-transparent fluid; in the larger ones the contents were more fluid, of a grayish color, sometimes brownish-red, from admixture with blood. A distinct limiting wall, sometimes dense and hard, is found in the larger abscesses, but it has not been seen in the smaller ones.

The fluid of the smaller abscesses is composed of fatty, granular material, fragments of liver-cells, and pus or lymphoid cells; that of the larger abscesses contained fat, red blood-corpuscles, fragments of liver cells, and very few pus cells. Amœbæ were contained in both, but were more numerous in small and recent abscesses.

Other changes in the liver consist in extensive necrosis in the centre of the lobules, the capillaries and necrotic cells containing numerous leucocytes; but amœbæ are not associated with the necrotic process; they are only found in association with the abscesses.

Abscesses are found also in the lungs; they occurred in three out of eight cases, and were seated in the lower lobe of the right lung in every case. In two cases the lung abscess communicated with a liver abscess through a perforated diaphragm. The abscess cavity in the lung was surrounded by consolidated tissue of great extent, embracing the entire lobe. The consolidation is due to interstitial pneumonia. The contents of the abscesswere granular detritus, round lymphoid cells, red blood-corpuscles, pus cells, and amœbæ. A definite wall sometimes included the abscess. The amœbæ are more numerous in alveoli immediately adjoining the abscess, and in those places where the abscess is most rapidly advancing, and where there is no limiting wall of connective tissue; but all the neighboring tissues contain them.

These appearances are different from those found in any other disease, and show an individuality of lesion, associated with the presence of the amœba, which establishes amœbic dysentery as a distinct disease. The amœba is not an accompaniment but a cause of the destructive changes in the liver and the lungs; there is a relation between the number of the amœbæ and the activity of the process, and where the process is more recent the amœbæ are more numerous.

The attacks begin suddenly or gradually. In the former case a watery diarrhœa is followed by frequent stools of blood and mucus; there are tormina and tenesmus. In some cases blood and mucus may appear in the beginning. In cases of slow development, diarrhœal symptoms are present throughout, with intercurrent periods of constipation. In both forms there is no fever unless diphtheritic changes occur, or unless abscesses develop in the liver or lung. In more severe cases, with gangrenous destruction of the mucous membrane, the patient is prostrated, and the stools are putrid and contain fragments of necrosed tissue.

The symptoms are not uniform or characteristic, as in the catarrhal and diphtheritic forms; intermissions and exacerbations occur. Convalescence is slow. The duration is from two weeks to several weeks, but it may last months or years; it becomes a chronic disease.

Amœbæ are seen in the stools, floating in the fluid or clinging to fecal masses. They are more numerous in acute cases and in the periods of exacerbation. They disappear during convalescence, but may be seen in normal stools after the patient is well.

Treatment.—Popular favor in India still holds to the ipecacuanha treatment of dysentery. McDowell, after thirty-five years' service with the British Army, says that the horrors of dysentery are disappearing since this treatment has been employed. He gives a preparatory dose of twenty drops of laudanum an hour beforehand, and places a mustard-plaster over the stomach; twenty to twenty-five grains of ipecacuanha are given at bedtime. This treatment is to be given every evening, and no fluid is to be taken after it; by the third day blood and mucus have usually disappeared from the stools, and they are free from pain. Maclean says this mode of treatment has reduced the former mortality to from twenty-five per cent. to seventy-five per cent., and that it is the most simple, the most successful, the most conservative, and the least objectionable mode of treatment of dysentery. Year by year under this treatment the chronic cases are becoming more rare and hepatic abscesses less frequent.

Other observers, while not losing faith in the efficacy of this mode of treatment, urge its use in smaller doses. Its use in this country has been disappointing, and it has never come into especial favor, though many advocate its use in small doses ($\frac{1}{4}$ grain to 3 grains) every half-hour to an hour.

The experience of those who have had most to do with epidemic dysentery in this country, has led to a division of favor between the specific treatment by ipecacuanha alone and purgation by salines. A supposed portal congestion furnishes the theory for the purgative plan of treatment, although its good effects are confirmed by experience. The fact that the supporters of purgation advise the constant use of opiates afterward, and those who recommend ipecacuanha do not find it necessary to have recourse to them, gives ground for belief that the latter is the more successful method.

The removal of scybalæ in the early part of the attack, and toward the end of the more acute symptoms, is of unquestionable advantage in influencing favorably the condition of the inflamed mucous membrane. Daily purgation is not found so beneficial as was at one time believed, and when to give a purgative becomes one of the most perplexing questions, requiring much judgment and experience in its decision. The salines and castor-oil are the best. In those cases where the discharges are fluid, containing shreds of tissue and small clots, pointing to extensive colitis, purgatives are unsuitable; their use is confined to cases of catarrhal dysentery with small bloody and mucous stools. In amœbic and diphtheritic dysentery they are of less use.

Opium, so largely used in this country in the treatment of dysentery, has its place among proper medicaments, but its use is only to ease pain and quiet the patient; when used for any other purpose, or in large doses, its use is to be deplored.

Bichloride of mercury and salol have been favorably mentioned on account of their antiseptic properties. Ringer recommends the former in doses of $\frac{1}{120}$ to $\frac{1}{60}$ of a grain hourly. Salol is supposed to pass unaltered through

the stomach, and in the intestine to be broken up into salicylic acid and phenol; it is given in ten-grain doses every two hours.

Calomel, so long in favor in this affection, has of late fallen into practical disuse, though some few still hold that it is worthy of a place among the specifics and purgatives.

Treatment by Suppositories and by Rectal and Colon Injection and Irrigation.—The use of suppositories containing opiates and astringents, although at one time a common practice, is much less in favor than formerly. It is not desirable to destroy, or to limit to too great an extent, the tendency of the rectum to expel its contents. The retention of a decomposing fluid in the colon and rectum cannot but be a source of danger, and fatal general infection may follow. The disease cannot be cured by putting a stop to dysenteric discharges, and therefore suppositories used for this purpose are not to be recommended. After the action of a purgative an opiate suppository may arrest too free purgation and keep the bowel at rest with benefit, and after irrigation, also, advantages may follow upon the same principle, but the doses of opium should never be large. In attempting to control tenesmus the temptation is frequently to give too large doses, which induce narcotism and which involve great danger.

These same rules hold against following the once popular method of using injections of starch-water and laudanum, which may be of service with the limitations just mentioned, but as a routine treatment the plan is not without danger.

The injection into the bowels of large quantities of warm or cold water has many advocates. The sedative effect of water of a high or low temperature upon an inflamed mucous membrane is of undoubted service in dysentery. The only objection is to be found in the danger of over-distending the inflamed gut, and of adding to its irritability. Irrigation, by cleansing the ulcerated surfaces, by washing away the decomposing contents of the bowel, and by destroying bacterial life, gives promise of accomplishing a great deal more than by the mere injection of fluids into the bowel.

Cool or hot water may be used for irrigation, but if an antiseptic agent be added to the water there is an additional benefit.

Antiseptic irrigation may be practised with solutions of mercuric chloride 1 to 5,000, quinine 1 to 5,000 or 1 to 2,000, salicylic acid, thymol, carbolic acid, sulpho-carbolate of zinc, boracic acid, etc. The use of bichloride solution must always be attended with a certain amount of danger; precautions should always be taken so as to have a free exit.

Irrigation can be practised in the rectum or colon; in either case a soft rubber tube is passed into the rectum or is gently and gradually forced upward through the sigmoid flexure. This is by no means an easy task, as the instrument so readily turns on itself; an occasional examination ought to be made with the finger to see if this has happened. Experiments in the cadaver show that the smaller-sized rectal and colon tubes do not make their way as readily as those of larger size. The habit of injecting water, as the tube progresses, favors twisting; progression is more easily made if the bowel is empty, as the mucous-covered wall guides the instrument in the proper direction. In many cases the colon cannot be reached, and there is danger of perforating the ulcerated bowel if too continued efforts are made. One must be content, therefore, to pass the tube as far into the sigmoid as possible. The fluid is then allowed to flow in from a fountain syringe, or is thrown in by a Davidson; when six to eight ounces have entered, it is allowed to escape through the same tube. This process is repeated until a quart or more has been used, or until the water escapes perfectly clear. If the patient is in the dorsal position or on the left side, with the hips raised, gravity favors the entrance of the fluid. In most cases, and especially in bad cases, with putrescent fluid discharges, it is safer never to attempt to push the instrument beyond the rectum. Two tubes of different sizes are passed into the rectum; the smaller one admits the fluid, which escapes through the larger one. The irrigating liquid is injected rapidly and escapes at once; in this way the rectum can be emptied and cleansed in a few moments.

There is an important point in connection with this method which shows its advantages. In the worst forms of dysentery, where the colon is chiefly involved, the rectum is more or less constantly filled with a decomposing fluid filled with shreds; with each effort at stool the rectum is only partly emptied; the sphincter contracts and closes, retaining a certain amount of the contents. Irrigation secures a complete emptying of the rectum, washes it out thoroughly, and makes it antiseptic as far as can be done. Frequent repetitions of the procedure will sometimes arrest, at once, the frequent stools, and the patient may be made to have his evacuations only at the time of irrigation, the intervals being lengthened as he improves. In this way great suffering is relieved and the danger of general infection is avoided. The experience of the writer has convinced him of the great value of this method, as applied especially in cases with abundant fluid putrescent discharges.

Rectal irrigation may be used in this manner, at first, at intervals of two to three hours; as tenesmus diminishes and the desire for stool lessens, the intervals are increased to four or six hours; they are then gradually stopped, a relapse often following a too early interruption of the treatment. Even after all the dysenteric features of the dejecta have disappeared it is well to continue irrigation for several days.

If the tenesmus is great and the stools very frequent, an opiate suppository introduced into the rectum immediately after irrigation gives added comfort. But for intense tenesmus, combined with wakefulness, nothing answers so well as the subcutaneous injection of morphia.

In this article the attempt has been made to present the more recent views of dysenteric processes, and not to give a full exposition of the subject. Reference to the article on Dysentery in a former volume of the HANDBOOK will show that many parts of the subject have not been touched upon here, because very little has been added to our knowledge except in the differentiation of amœbic dysentery from forms already known and fully described, and in the improved treatment by irrigation.

William W. Johnston.

INTESTINAL SUTURE AND ANASTOMOSIS. The advance in the treatment of wounds of the intestine, whether they be made by accident or by the surgeon in resecting or incising the bowel, is coincident with great surgical activity in the field of abdominal work. The possibilities of safe and perfect work have increased.

The details of methods devised by many operators have multiplied until the practical surgeon is bewildered in choosing a method suitable to each emergency he encounters. The technique of some of the methods proposed is elaborate, of others comparatively simple. It may be said that in the hands of each author the method advocated by him has resulted in a measure of success, seeming to warrant him in launching it upon the ocean of surgical endeavor, strewn already with more wrecks than sailing craft. It is to be assumed that, unless a method meets with a goodly share of success in the hands of general surgeons everywhere, the appeal of any one advocate will not entitle it to a permanent position in the armamentarium of the well-equipped surgeon. Many methods are highly ingenious and appeal to the fancy of the student rather than to the utilitarian mind of the operator.

It is difficult, with the improved statistics of abdominal surgery, to know how much value to place on the help obtained in saving life by the novel methods of intestinal repair, and how much on the general knowledge of the treatment of all abdominal wounds *per se*.

Statistics of the past cannot be compared with those of recent years, because of the marked causes of former mortality from peritonitis due to infection of erysipelas, sponge and hand contamination, and sepsis, now happily so largely eliminated from our hospital operating-rooms.

The mechanical part of intestinal suturing will, therefore, concern us rather than the results as judged by the scant statistical records. The really important part of this work is a matter of contemporary surgery.

Prior to the past twenty years, recovery from injury of the bowel bordered on the marvellous, even to the mind of the older surgeons. True, an occasional recovery is recorded of successful treatment as far back as 1521, when an unknown surgeon sewed up a stab wound of the stomach and the patient recovered.

Now, we know that with strictly clean work a surgeon can, for all practical purposes, insure perfect healing of sutured wounds of the alimentary tract. His duty is first to know the simplest technique of the few useful methods of stitching, and then the application of them to more complicated methods.

His first concern is with the material used—the needle and thread. I believe nothing more perfect than the ordinary cambric needle can be used. Yet a small Hagadorn or a glover's needle may be employed in the absence of the other. The cutting edges of the latter wound the many veins of the bowel, and are pretty sure to make troublesome interstitial hemorrhages which dissect the coats for some distance from the puncture points. The round cambric needle, on the other hand, enters the tender intestinal coats readily and stops at the resisting submucosa, which, as Halsted has shown, has a definite fibrous quality which can be detected and picked up on the point of this needle, thus giving a more secure purchase for the thread. The needle should be long enough to be readily handled—one and three-quarters or two inches is the best length.

The thread should be of fine silk; No. 00 embroidery silk, iron-dyed, is best. In emergency, however, one may use common linen thread perfectly well, though it is not so smooth nor so readily drawn through the tissues as is silk. It has the advantage of being obtained of proper strength and size in an emergency, in any household, as is the needle also.

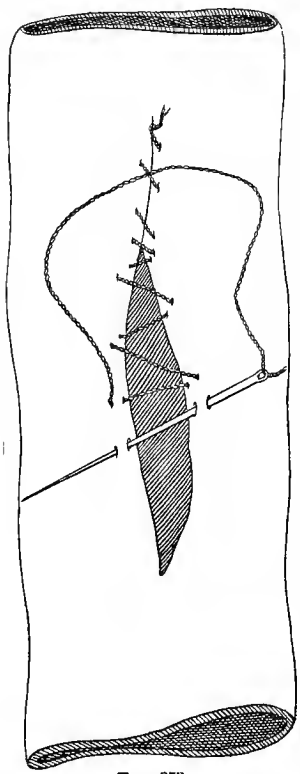

Fig. 353.

Catgut is not to be used in intestinal suturing. It is not enduring enough, its knots slip, and its sterilization is not to be trusted as perfectly as is that of silk or linen. The needle should be sterilized by passing it through the flame of a lamp three times. The thread is perfectly sterilized by boiling, after winding it on a small glass rod. Boiling for a half-hour and immersing in alcohol until needed, is the best method for preparation. It may, however, be sterilized by dry heat for three hours (oven-baking temperature, 300° F.) and kept in cotton-stoppered test-tubes without fluid, thus making it light and portable.

Safe and accurate apposition of the edges of the intestinal wound depends on the variety of stitch employed, and it is well to fix in one's mind two or three varieties of suture that have stood the test of experience, and discard all others as unnecessary.

The principle underlying the inducing of sound adhesion of the wound is that fixation of two peritoneal surfaces in contact, by means of some slight traumatism or the presence of a foreign body, such as the suture, immediately causes the copious exudation of plastic lymph, which seals the layers in from two to six hours, so that leakage is impossible without violence. To further add to the solidity of the lymph, it has been shown by Senn that gentle abrasion of the surfaces before sewing causes additional firmness to result.

The suture must take hold only on the peritoneum, the muscular coat, and an attenuated but firm and readily recognizable submucons fibrous reticulum, without penetrating the mucous coat.

The action of the circular and longitudinal muscular fibres causes a double movement of the part involved by the stitches, so that absolute fixation is a matter of skill in the use of the stitches. The stitches to be considered are the Lembert or "interrupted," the "continuous," and the quilt stitch. The "Czerny-Lembert" is characterized by the use of a separate suture of the mucous coat within the bowel, combined with the Lembert externally.

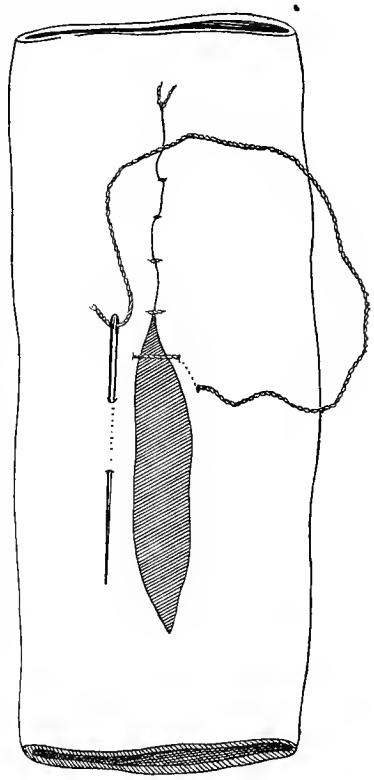

Fig. 354.

The continuous suture, as modified by Cushing, of Boston (Fig. 354), gives a method by which excellent apposition is obtained and the thread more thoroughly buried in the intestinal coats than in the simple running suture of Dupuytren (Fig. 353). When we consider the fact, however, that all these sutures turn in, and keep in contact two lips of intestinal edge which act as a valve when pressed from within, allowing nothing to escape so long as the suture holds, it seems that one has no advantage over the other from a mechanical point of view. It is argued that the lengthening and shortening of the wound by reason of the double peristaltic muscular action might allow such relaxation of the continuous suture as would cause a gap for leakage between successive stitches. Practically, this would be quite as likely to happen after the use of the interrupted suture. But in reality it never does happen after either one. What does happen occasionally, when one row is used alone, is, that some single stitch in the line gives way, owing to its insufficient hold, allowing it to cut out, and then an eversion of the mucous membrane and leakage occur. This is a uniformly fatal mishap,—hence all experience shows that a double row is needed to secure perfect union. Each row should have about six stitches to the inch and the rows should be parallel to the cut edge—one-sixth of an inch apart. With this double row carefully applied, no sutured opening can leak.

The time occupied in making a running suture is one-third that of the interrupted, and it is therefore coming into vogue as the most desirable.

The choice of sutures for the different rows lies with the operator. The interrupted Lembert has had preference in the past. It is acknowledged to take three times as long to apply as the continuous, and

is therefore being displaced by the latter in suitable cases.

After an extensive use of all methods in living subjects, having regard both to security and time, I prefer to apply a quick-running Lembert suture (Fig. 353) nearest the cut edge of bowel, and outside that the Halsted "quilt" suture or its modification (Fig. 356).

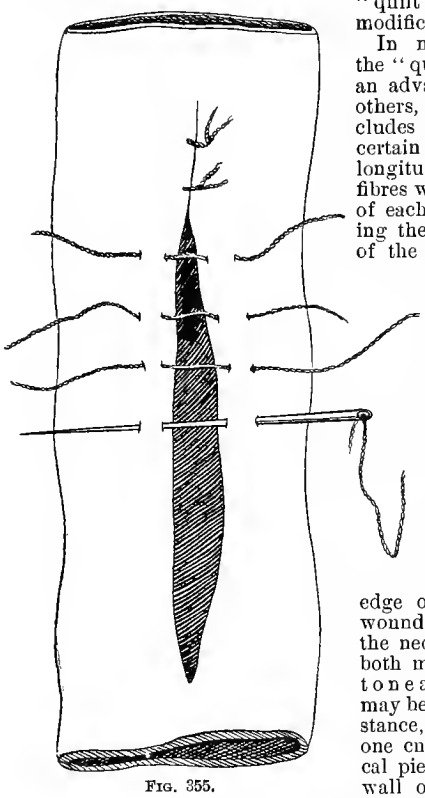

Fig. 355.

In my observation the "quilt" suture has an advantage over all others, in that it includes and ties up a certain length of the longitudinal muscular fibres within the grasp of each knot, thus fixing the definite length of the wound beyond the power of its elongation or shortening during repair. This point has not heretofore been emphasized, but it is one of importance.

There are times when a continuous suture "overhand" may be taken, of the edge of a stomach wound, for example—the needle penetrating both mucous and peritoneal coats. This may be utilized, for instance, in a case where one cuts out an elliptical piece of the entire wall of the organ to include an ulcer, or a neoplasm. It is found that the wounded edge, being thick and vascular, requires many points of clamping. It is here safe and advantageous to suture the edge as above to check hemorrhage and secure the edges. This thread then becomes turned entirely into the stomach when the outside sutures are applied.

It is of interest to observe what becomes of the threads. They all, even the continuous sutures, seem to work toward the cavity of the viscus by natural law. One end having become free, the remainder is soon cast off into the bowel. From two to six or eight weeks is usually enough time for them to work free.

Experience goes to show that if the thread, needle, and operator's finger are sterilized, there is not much to be feared from sepsis due to intestinal contents. At least, careful rinsing of the parts sutured during the operation—with plain boiled water—gives non-suppurating results, and stitch-hole abscesses must occur infinitely less often than in the case of the skin, unless the mucous membrane be involved. Where the thread penetrates and secures two edges from mucous membrane to mucous membrane, it acts as a seton, and as the inflammatory fluids exude they drain into the bowel—thus doing no damage,—provided the adjacent peritoneum is well secured by the outside row of stitches catching up only peritoneum.

To Dr. Nicholas Senn is due the credit of a thorough and exhaustive experimental study of the subject of intestinal repair, and to him will ever be credited the addition of certain aids to operative work. Abrasion of the approximated surfaces has been mentioned. Omental grafting, so called, will stand as a useful adjunct.

It has been shown by Schede and others that the peritoneal cavity will tolerate the presence of considerable masses of living tissue, such as pieces of muscles, or even cancer tissue, deposited in an aseptic state, free within it. Such pieces, quickly blanketed by a layer of lymph, are soon vascularized and digested, as it were.

If a strip of omentum two inches wide, and as long as needed, be torn from the edge of the patient's omentum, wrapped round the sutured bowel, and tacked in place by three or four sutures, it quickly becomes adherent to the parts underneath and acts as a reinforcement to the junction. This is the so-called "omental graft."

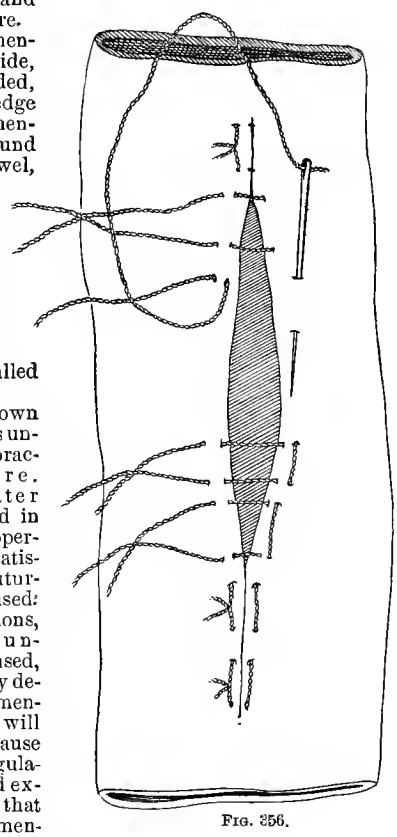

Fig. 356.

It has been shown to be useful, and is unquestionably a practical procedure. Whenever greater security is needed in cases where the operator is not quite satisfied with his suturing, it should be used. In most operations, however, it is unnecessary. If used, it must be entirely detached from its omentum, otherwise it will leave a band to cause internal strangulation. Senn found experimentally that such grafts of omentum became firmly adherent in from twelve to eighteen hours, and were freely supplied with blood-vessels in from one and a half to two days.

Having settled in our minds the best methods of suturing simple wounds of the intestine, we turn to the variously complicated conditions which the surgeon is called upon to meet. They consist of either gunshot wounds, perforating ulcers, obstructions, tumors, stenoses from contractions, kinks or twists, or resections for destroyed portions of bowel, as in hernias, or old fecal fistulæ.

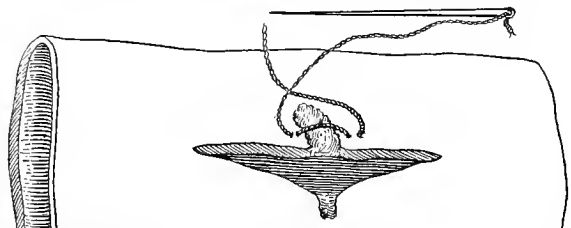

Fig. 357.

In considering these maladies we may, for the purposes of this article, regard the intestine as either the subject of a lacerated wound or ulcer, or as resected after one of the diseases named, and study the best methods of repairing the lesion.

For a lacerated wound or a gangrenous perforation one may split the intestinal wall an inch and a quarter in each direction from the perforation, lengthwise, and, bending the bowel, make an elbow at this point, turning the ulcer in and bringing the cuts together where they are stitched about, so as to restore the continuity of the bowel.

I have done this in a case of gangrenous ulcer transverse to the bowel, where it had been held under the sharp inguinal ring (Figs. 357, 358, and 359). The alternative of resection or artificial anus was avoided, and the patient was restored immediately to perfect health, which she has maintained for four years past.

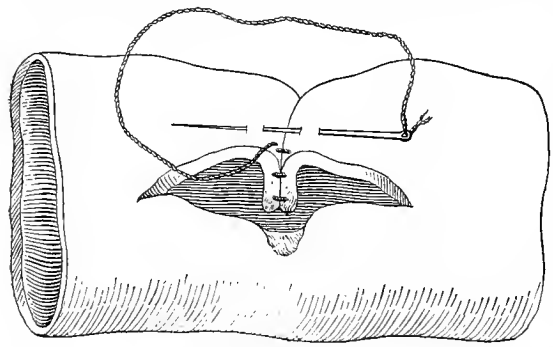

FIG. 358.

For impending perforation, instead of resecting or suturing, one may adopt Chaput's suggestion of stitching a convenient piece of adjacent intestine to the ulcerating surface, thus protecting the peritoneal cavity and insuring its safety in case the perforation follows. In such an event the attempted discharge through the ulcer would be thrown back into the bowel from whence it came, or if it perforated through the piece of bowel plastered up against it, there would be only a fistula between bowels which would soon close spontaneously.*

If a portion of intestine is torn in dissecting it from an inflammatory association with a tumor, the abdominal wall, or another piece of bowel, the degree of tearing will determine whether to suture or to resect, or to form an artificial anus temporarily. A small tear should always be sutured at once, if feasible. If the tissues are in a bad state and it is doubtful whether the sutures can be relied on, the wound should be tamponed with iodoform gauze for thirty-six hours. At the bottom of the wound is the wounded bowel. If when the tamponade is removed the lymph has sealed the wound, nothing need be feared, no replacement of the tampon is needed — at most, a small drain may be established through the abdominal wall; and to insure prompt union between the parts displaced by the tamponade, all that is required is to bring them into close contact. On the other hand, if leakage from the bowel occurs, it will form a fecal fistula which will, in nine out of ten cases, spontaneously close in a few weeks.

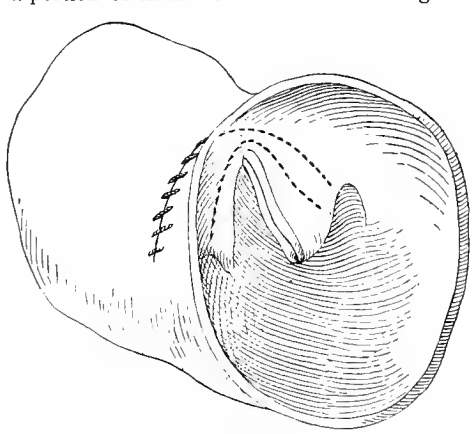

FIG. 359.

If, after a fecal fistula has formed, the edges of the abdominal wound and the surface of adjacent skin become quickly excoriated from the intestinal juices, it is an evidence that the portion of bowel which is wounded is situated high up toward the stomach, even though the loop seemed to be anatomically as low as the supra-pubic region. The seemingly acrid secretions, though really of alkaline reaction, have so powerful a digestive capacity, that they do not spare the horny non-vascular layer of skin, and only stop at the papillary. The most exquisite pain follows from exposure of the nerve-ends in the skin. I have tried everything to relieve this distress and tide the patient over the few weeks during which the stenosis goes on so surely, and I have found no remedy as good as zinc ointment smeared on the cleansed skin, over which is laid coarse surgical gauze, in small compresses so disposed as to confine the discharge well. Simple spreading of salve cloths is useless, but the superimposed compresses draw away from the skin the discharging intestinal juices, and only the lowest layer, which soon becomes neutral, touches the tender skin. All other methods than the above I have found to fail.

I will not consider here why, when, or where the surgeon has to resect portions of intestine, but will review his resources for restoring the continuity of the canal, after he has resected a complete piece of the intestinal tube.

For the history of the earlier adventurers in this field one may refer to works on general surgery, such as Treves's "Manual of Operative Surgery."

Practically, at present, we have a choice of three methods to accomplish our purpose :—

First. End-to-end union.

Second. Lateral implantation.

Third. Lateral anastomosis.

Each method is capable of being done by sutures alone, or we may use artificial mechanical devices aided by sutures.

The ideal result would undoubtedly be attained by end-to-end union, if possible, without narrowing the canal. Practically, however, the operator has to consider the security of his suturing and the time consumed by this method.

When intestine is cut across there is a part lying beneath the mesenteric attachment which has no peritoneal coat. When this is sewed to the corresponding part of the other end, the reparative lymph thrown out from the peritoneal surface is wanting here, and it is therefore the point at which fatal leakage of fecal matter often takes place.

This can be avoided by extreme care, as follows: Place an independent stitch at the cut edge of the mesentery close to the bowel, uniting its two layers. This practically makes the peritoneal coat continuous around the circumference.

Two layers of sutures are essential: one of the mucous edges only, which must be knotted on the inside; the second, limited to the peritoneum.

In this, the so-called Czerny-Lembert suture, the continuous suture is not available, because, if tightened securely enough, it acts like a purse-string, and leaves an annular stricture. The time consumed in making the circuit of the bowel by interrupted sutures, a double row, is very great, amounting to from an hour and a half to two hours, in thoroughly perfect work. The result, however, when complete, leaves nothing to be desired.

One risk must be borne in mind, namely, that if the

* This method of Chaput (Gazette des Hôpitaux, 1892, No. 138) applies as well to torn or gunshot wounds of the bowel, and may on occasions prevent a resection. It requires nice judgment, however, on the part of the operating surgeon to choose between these methods. In badly torn wounds, especially if a bullet traversed the gut, I would prefer the resection and lateral anastomosis, as described later on.

arterial supply coming to the cut edge from the mesentery is interfered with by too close suturing there, where it is most demanded, there is danger of gangrene of the sutured edge, with late extravasation of fæces. This is due to the anatomical fact that the arterial circulation in the intestinal coats courses around the bowel and not lengthwise of it.

With fifty per cent. of deaths from this method in the

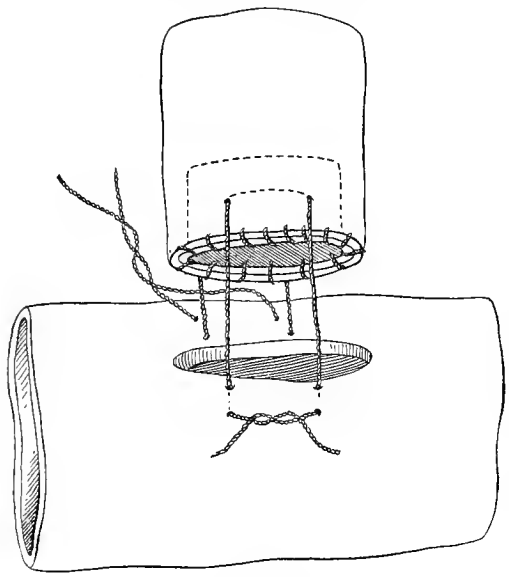

Fig. 360.

hands of good operators, it is not surprising that we have to turn to less tedious and dangerous methods.

End-to-end invagination has been advised by many—in imitation of the accident of intussusception. The distal divided end is first inverted, and the proximal drawn into it by two sutures fixed to its peritoneal edge, thrust into the lower end, and brought out on its surface where it is temporarily secured, while a series of circumference sutures is applied to the edge where the inverted cuff of the lower lies against the surface of the upper end.

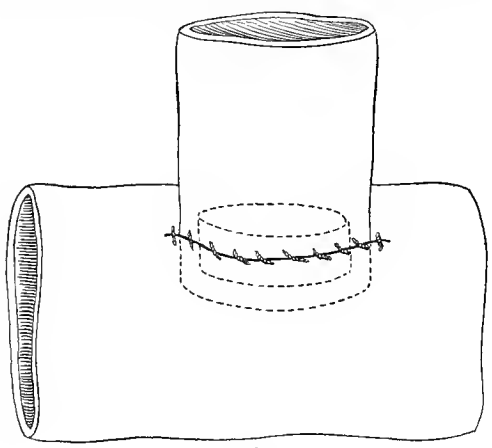

Fig. 361.

This method has been very successful in canine experimentation, and may be used successfully in men. It is likely to get blocked by the obstruction of the thickened coats plus the food products, and thus be pushed on by peristalsis and beget a severe and genuine intussusception.

A modification of this method consists in stripping the mucous membrane from the inside of the distal end for a half-inch or more by curette, and stitching the proximal end into it so that the serous membrane of the latter is stitched to the freshened interior of the distal end.

This has been found to work well in dogs' intestines, but it seems a perilous method to use in the relatively thinner human bowel, where much depends on the maintenance of perfect circulation in the edge.

Where resection of a stricture has been performed, or a malignant growth has been excised and the tube of bowel above is dilated to a much larger size than that below, Wehr has suggested that the smaller be trimmed obliquely, so as to match the second in diameter, and then the stitching of two equal openings, one circular, the other oblique, can be accomplished by double suture. This jointure will make a wide angle elbow in the course of the bowel, but not one that would be disposed to kink. The oblique cut being made at the expense of the side opposite to the attached mesentery, there would be no danger of a sloughing edge from interrupted blood-supply.

The second method, of "lateral implantation," is in

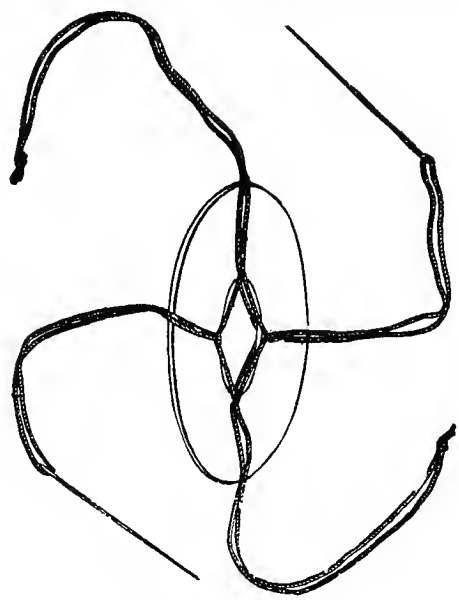

Fig. 362.—Senn's Decalcified Bone Plate.

imitation of the normal anatomical relation of the ileum to the caput coli.

If we have a free end of the ileum left after a resection near the colon, we may resort to this simple procedure after the method first devised by Jobert, but best modified by Senn, as illustrated herewith (Figs. 360 and 361). This method may be described as follows:—

A flat band of rubber is stitched by the edge on the inside of the proximal gut to hold this firmly open. A slit is made in the colon, and by two stitches, one on either side, taken like large quilt stitches, the small end is drawn into the large bowel, whose edges are inverted thereby. A continuous suture is made around the line of meeting, thus shutting it off perfectly. This method is not tedious and deserves attention. Whether the aperture would tend unduly to close later, or whether intussusception would take place from peristalsis, and blocking ensue, cannot be said. To this method may be applied some of the aids mentioned later, such as bone buttons, etc.

In lateral anastomosis we have a method that has a great field of usefulness in the future. The operation essentially consists in establishing an opening between two adjacent portions of bowel tightly secured together, thereby switching off the intestinal contents to another channel.

The proposition of thus making a short circuit for the intestinal fluids originated with Maisonneuve, who practised the method on two patients, who died. This discouraged further efforts to perform the operation. It was not resorted to again until 1881, when Billroth and Wöllfler each operated on a case of pyloric stenosis from cancer, by establishing an opening between the stomach and small intestine, calling the operation gastro-enteros-

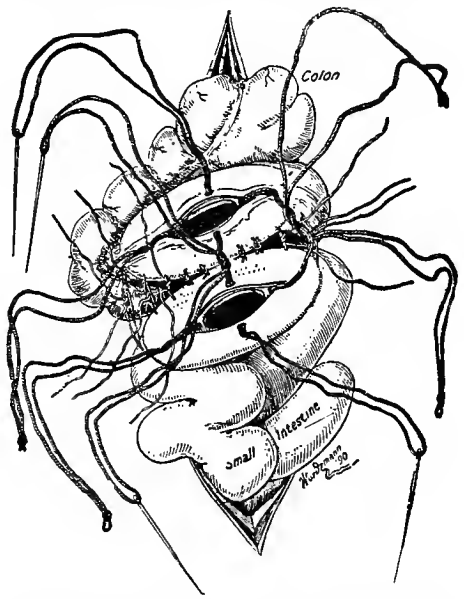

FIG. 363.—Ileo-colostomy with Decalcified Bone Plates, showing plates in position, one in the ileum, the other in the colon.

tomy. Since then it has been widely used. To obviate the tedious suturing of the openings, Senn, of Milwaukee, used disks of decalcified bone (after trying all other absorbable but firm substances) for the purpose of approximating the serous margins about the anastomotic openings. His two objects were, first to save time, second, to make safe apposition.

That the principle of lateral anastomosis has been universally accepted by surgeons as worthy of adoption, is proved by the energy and ingenuity shown by operators everywhere to modify and simplify the technique. The two objects aimed at have been to save time and add security. Up to the present writing, no device has shown itself better than Senn's bone plates in saving time.

These aids are made from the hard bone of an ox thigh sawed in a plane so as to make a bone plate three inches long, an inch wide, and a quarter-inch thick. This is soaked twenty-four hours in ten per cent. hydrochloric acid, to decalcify it. A brief washing in alkali removes the acid. The pliable bone can be cut with a penknife. A hole is made in the centre an inch and a half long, and four small holes are drilled beside it. Threads are now secured in it as shown in the diagram (Fig. 362), and the plate is kept in a solution of equal parts glycerine, alcohol, and water, ready for use.

The mechanical part of its application is extremely simple. The two parts of bowel to be joined are drawn up into view and confined by compresses of gauze or damp towels. An incision is made lengthwise of each bowel an inch and a half long, opposing each other, and into each opening a bone plate is slipped. A needle having been threaded with each of the two side-threads, is to be carried through the plate and the edge of the cut from within outward. This secures the plate against slipping. The two end-threads lie in the angle of the cut. The same is done to the other plate. The two plates being then in position, a half-dozen Lembert stitches are placed behind the plates to secure the coats of the bowel together where the edges of the plates press them together. The plates are then laid together, and the edges of both openings are thereby tightly sandwiched between them, when the four strings are tied in strong, square knots. These knots are cut short and tucked in between the plates. The intestinal edge being so slippery, will often be squeezed out between the plates; hence a few outside Lembert sutures, or one continuous suture, are needed to complete the operation. Senn advises a light abrading of the peritoneum between the plates before tying.

The excellence of the method has been proven by many successful cases, I have myself used it with perfect satisfaction in the case of a carcinomatous stricture of the hepatic flexure of the colon, in which, after twenty-five or thirty pounds of soft fæces had been evacuated by inguinal colotomy, and ten days had been allowed for recuperation, I united the ascending and transverse colon by lateral anastomosis, by means of Senn's plates, with perfect success. Six months later, the man died of cancer, and I found the opening I had made had contracted to a small orifice only large enough to allow fluid fæces to pass, hence requiring him to use laxatives for three months before death. The original aperture was an inch and a half in diameter. I felt the need of making larger apertures than the plates allowed, and devised the catgut rings, which have since been used with great success by many operators. This was the first modification of Senn's device, and has the double advantage of being made large (the opening measuring two inches in length) and of not interfering with the course of fæces through the aperture from the moment of operation. This device has been used many times with perfect success in grave cases of lateral anastomosis, and has usually required twenty-five minutes for complete adjustment. Senn's method can be satisfactorily done, when everything is prepared, in fifteen minutes; but I consider the small aperture obtained, the blocking by bulky plates, the leaving of complicated knotted threads attached to the wound, the imposition, upon the sensitive intestine, of a mass of comparatively indigestible foreign substance, the removal of which is to be effected by peristaltic action, which causes a tugging at the wound, as a menace to perfect security that is illy compensated for by a gain of five or ten minutes' time over another method by suture alone, to be described further on.

Among many modifications of Senn's bone plates published later, I may mention Brokaw's segmented rubber rings ("Trans. Southern Surgical and Gynecological

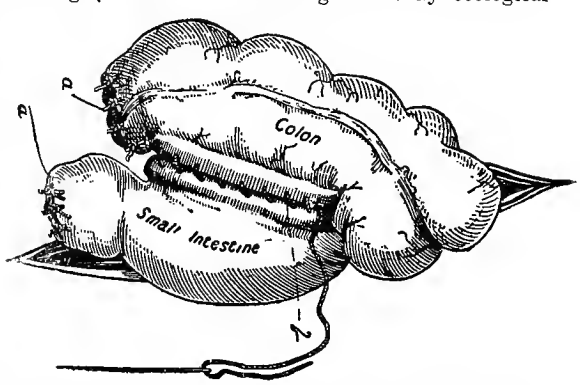

FIG. 364.—Ileo-colostomy without Resection of the Cæcum, showing plates in position, one in the ileum, the other in the colon.

Ass., November, 1889"); also Robinson's rawhide plates, made of a long disk of beef's hide, shaved, macerated one day in saturated salt solution, then dried, cut into shape, threaded, and kept in alcohol until used. This material has been found serviceable.

Davis's catgut mats (*Virginia Med. Monthly*, September, 1889) were devised later, and have been used, but the author of them has abandoned their use.

Dawbarn advises oval rings, cut from raw potato, to be used much as Senn's plates are, and claims that they ought to remain firm twelve hours, which would give time for plastic adhesion to be fairly secure. He adds to the usual technique two features that seem unnecessary and unwise, namely, the use of hydrostatic pressure through one of the open ends of bowel, to test the security against leakage after the plates are tied in; and, second, the introduction and fixation of the plates through the open ends of bowel, and cutting of the anastomotic opening through both walls of the bowel at once by a knife passed into one open end (*Annals of Surgery*, February, 1893).

Jessett, of London, has devised a bone plate like Senn's, with a cylinder of bone fitted into the central hole. This pushes into the opposite plate hole and secures the exact fixation of the plates, with the addition, of course, of some suturing.

Baracz has devised plates of raw turnip, which he has used successfully on the human subject, the anastomosis occupying three-quarters of an hour. They are like the potato, hard, easily prepared, and do not tear (*Centralblat. f. Chirurgie*, July 9, 1892).

Mayo Robson has devised a spool of bone, or "bone bobbin," as he calls it, having a diameter of an inch, over which he sutures the bowel ends in end-to-end union, or inserts it in lateral implantation.

Murphy has devised metallic buttons of oval shape, whose stems clinch each other when pressed together after the button part has been passed into the lateral opening in the bowel, and thus pinch the involved walls

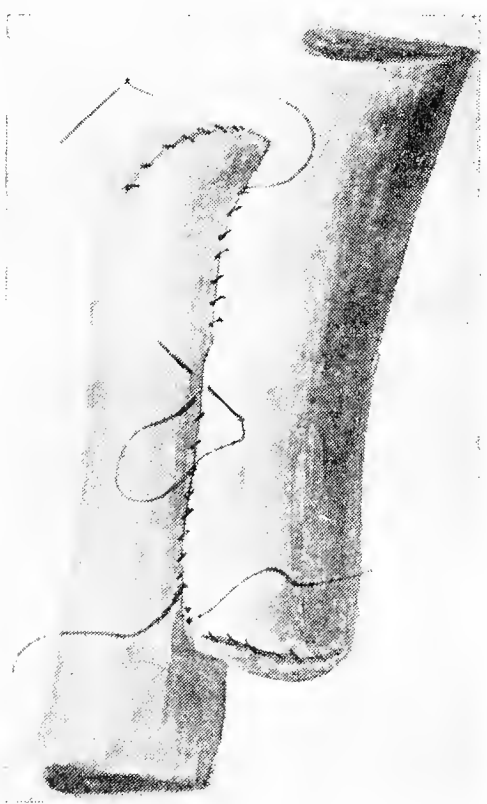

FIG. 365.—Suturing Intestines in Apposition before Incision.

so that adhesive inflammation is engendered at the margin of pressure, and this sloughs when the united buttons come away. This device he has used to produce quick anastomosis between the gall-bladder and intestine, as well as between two different portions of the bowel (N. Y. *Med. Rec.*, December 10, 1892).

Thus the devices multiply, and in the hands of each inventor success is reported.

The writer has tried many of the devices upon animals and the human subject, and with what is commonly called brilliant results. Yet it seems to him that perfect work, after all, follows the use of the suture alone.

FIG. 366.—After a Four-inch Incision and Sewing the Edges.

Improved technique of lateral anastomosis by suture gives a marked shortening in time. Twenty minutes have sufficed on several occasions to complete thorough anastomosis in human subjects.

The operation should be conducted as follows: Let us suppose resection to be called for. If the bowel has fæces in it, a ribbon of iodoform gauze is drawn through a small wound of the mesentery at the bowel edge, some inches above the trouble, and tied about the bowel so as just to stay the flow of fæces. The resection is quickly done with scissors, and the cut ends inverted by a double row of continuous fine black silk suture.

The two ends are then overlapped four inches or more, or laid side by side with ends together, as may be most convenient. I have tried both methods on the human subject, and cannot see that the results are less perfect either way.

Several needles are prepared, armed with fine black silk twenty inches long, tied with a double knot at the eye of the needle, and with one end cut off one inch from the eye.

Two rows of continuous suture of the peritoneal and muscular coats are made, about four inches long and one-quarter inch apart (Fig. 365). An opening is now made with blunt-pointed scissors parallel to the sutures, and an eighth of an inch from them, leaving both rows on one side the cut. The latter should be between three and four inches long. Some bleeding points may now need clamping.

A fresh thread and needle are now made to secure both the cut edges next the sutures together; a simple overhand suture is best (Fig. 366). It arrests all hemorrhage, and the clamps are removed as the needle reaches them. The stitch is now made to quickly overhand each free edge by itself.

We have thus far made two long button-holes, secured on one side by three rows of sutures. It remains only to rinse the parts with pure water and continue the two outer rows around the still unsecured edge. This is easily and rapidly accomplished (Fig. 367).

On one side of the opening are three rows of stitches, which give great stability to the union, especially as the

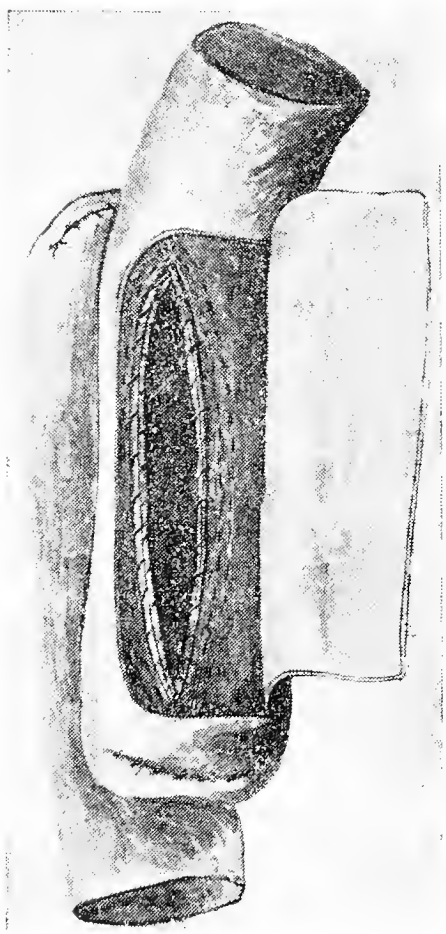

Fig. 367.

innermost includes the entire thickness of both edges. This is especially a strong point in uniting bowel to stomach (gastro-enterostomy), inasmuch as the disposition of both viscera to sag away from each other brings a little added strain on the back of the union.

Anastomosis thus done may be tested by water pressure, and will be found never to leak.

The question of time gained, during what is usually a prolonged operation—perhaps five or ten minutes' gain, at most, in the face of the uncertain advantage of plates, rings, buttons, and bobbins—is one that in the author's opinion is greatly outweighed by the superior advantage of having absolute security against leakage, blocking, etc., by the method of simple suturing. The technique of the latter procedure is a matter of easier accomplishment and far greater satisfaction in its results than that of the newer methods.

The absence of all paraphernalia but scissors, thread, and needle, makes the procedure most attractive.

There is one feature of the lateral anastomosis operation which has been largely overlooked, but which the author believes to be of the greatest moment in determining the lasting benefit of the operation; that is, the question of stenosis of the newly made orifice.

The law of cicatricial contraction, which operates so effectually in closing accidentally made fistulæ into the intestinal tract, or comparatively large ulcerations between the gall-bladder and the intestines, is here the direct antagonist of the surgeon in his endeavor to create a permanent and adequate anastomotic opening.

The incised opening for Senn's plates is about an inch and a half in length, for others it is still smaller, and the contraction of such an opening, sometimes with great rapidity, has in some cases rendered it entirely inadequate to its service. Not many autopsies remote from date of operation are recorded.

Three of my own cases of lateral anastomosis illustrate my point admirably. In the first, done in 1888, where I united the transverse and ascending colon by Senn's plates, the patient lived six months. The aperture had contracted from an inch and a half down to three-quarters of an inch, and the man required constantly to use laxatives. In the second, where I united ileum to ileum by catgut rings, the patient lived six months. The contraction reduced the opening from an inch and a half to one-half inch. In the third, eight months after lateral anastomosis of the sigmoid flexure following resection, the aperture of three inches contracted to one and a half. This was perfectly competent to do the functional work of the bowel.

These results were relatively good, but two cases done after the suturing method above described, around openings of between three and four inches in length, have maintained perfect functional action for over a year and a half.

I believe the future utility of lateral anastomosis lies in making these long openings. This, I think, is almost impossible with bone plates, and only to be done with very long rings or vegetable plates, and then only with less security and with the consumption of as much time.

The contrast is enormous between dropping back into the abdominal cavity a beautifully sutured, absolutely tight and flexible anastomosed end of intestine to any position in the abdomen which its natural surroundings demand, and returning a huge, stiff bunch of bowel, inside which there is a pair of big plates of bone or raw potato, to remain as irritating foreign bodies, stimulating peristalsis, and tugging at the wound until they become softened enough to be swept on by the current; or, as in one of Dr. Senn's cases, to be vomited up after dangerous retching.

As regards time, even were it proven that a hand equally expert at each method could do that by plates a few minutes quicker, the relative advantage of the two procedures for safety would still lie with suturing.

But, as a matter of fact, I have found that to do thoroughly a lateral operation in the living subject, by either plates or rings, takes twenty or twenty-five minutes, and the same operation by simple suturing, done with the greatest nicety and perfect security, has taken me twenty minutes.

In conclusion, the author still feels that what gain has been made in intestinal anastomosis and suturing is due to improved understanding of the needs of aseptic work and intelligent handling of the viscera; that the attempt to simplify the technique of lateral anastomosis by plates, rings, and the many devices extant has not improved it; that lateral anastomosis is, in most cases, the speediest, safest, and best method of restoring the canal; that simple and thorough suturing with fine silk continuous suture, after the manner detailed, is the most satisfactory; that, in order to allow for the inevitable tendency to stenosis, an aperture nearly four inches long should be made between bowels; that, while it may assist in fortifying the lymph union, abrasion of the opposed surfaces of peritoneum is not necessary to quick and solid repair. *Robert Abbe.*

INTESTINES, WOUNDS OF Intestinal wounds depend on the same causes as wounds elsewhere. The injury usually comes from without; rarely, it is due to a foreign body in the intestinal canal.

Each anatomical division of the intestinal tract is liable to injury, but those portions that are most extensive or most exposed are obviously in greatest danger. For these reasons the ileum and jejunum suffer most frequently, the colon occasionally, the duodenum least of all. In contusions, however, the duodenum seems to suffer a little more frequently than the colon. The latter, especially its vertical portions, has but a limited range of motion, and is therefore poorly protected against traumatic influences. It possesses, however, the immunity afforded by a deep location, comparatively limited use, and dense protecting structures.

The mobility of the intestines, due to their lax attachments and to the peculiar nature of their investing membranes, their elasticity, and the yielding nature of the tissues about them, affords the greatest possible natural immunity from violence that is consistent with the proper performance of the functions of the human body.

While in normally developed adults the divisions of the intestine present no decided variations from each other in their relations to the abdominal wall, yet Treves has shown it to be impossible to definitely localize any certain portion of the jejunum or ileum by external examination. In Treves's own words, "there is no systematic arrangement of the coils of the small intestine. There is a disposition for the bowel to follow an irregularly curved course from left to right, but this disposition can never be relied on. Such as it is, it may be expressed as follows: The gut starting from the duodenum, will first occupy the contiguous parts of the left side of the epigastric and umbilical regions. The coils then fill some part of the left hypochondriac and lumbar regions. They now commonly descend into the pelvis, reappear in the left iliac quarter, and then occupy in order the hypogastric, lower umbilical, right lumbar, and right iliac regions. Before reaching the latter situation, they commonly descend again into the pelvis. The coils found in the pelvis belong usually to the lower ileum and to the bowel, between two points respectively six and twelve feet from the duodenum."

Causation in General.—The violence coming from without, or arising within the canal, may be called the *exciting*, while the habits, occupation, idiosyncrasy, and surroundings of the patient are the *predisposing* causes. The nature of all intestinal wounds usually indicates the cause, though a single form of violence may produce a wound of multiform characteristics. The direction and degree of the force, the magnitude and character of the agent transmitting it, determine the extent, and largely also the number and variety of the wounds inflicted. The direction of a wound of the intestines, as well as the size, exerts an important influence on its local physical phenomena.
